- Improve treatments and expand access to care: integrate screening and core packages of mental health services into routine primary health care; reduce the cost and improve the supply of effective medications
    - Develop effective treatments for use by nonspecialists, including lay health workers with minimal training
    - Incorporate functional impairment and disability into the assessment
    - Provide effective and affordable community-based care and rehabilitation
    - Improve children’s access to evidence-based care by trained health providers in LMICs
    - Develop mobile and IT technologies, such as telemedicine, to increase access to evidence-based care
- Raise awareness of the global burden of untreated illness

    - Develop culturally informed methods to eliminate the stigma, discrimination, and social exclusion of patients and families across cultural settings
    - Establish cross-national evidence on the cultural, socioeconomic, and services factors underlying disparities in incidence, diagnosis, treatment, and outcomes
    - Develop valid and reliable definitions, models, and measurement tools for quantitative assessment at the individual and population levels for use across cultural settings
    - Establish shared, standardized global data systems for collecting surveillance data on the prevalence, treatment patterns, and availability of human resources and services
- Build human resource capacity: increase capacity in LMICs
    - Create regional centers for mental health research, education, training, and practice that incorporate the views and needs of local people
    - Develop sustainable models to train and increase the number of culturally and ethnically diverse lay and specialist providers to deliver evidence-based services
    - Strengthen the mental health component in the training of all healthcare personnel
- Transform the health system and policy response: establish and implement minimum healthcare standards for mental disorders around the world
    - Redesign health systems to integrate mental disorders with other chronic disease care
    - Create parity between mental and physical illness through investment in research, training, treatment, and prevention
    - Incorporate a mental health component in international aid and development programs

Global Mental Health

The basic tenet of the GMH movement is that every person in the world has an inherent right to mental health from a CEI and social justice perspective. There has been a focus on addressing treatment gaps by scaling-up evidence-based interventions and increasing access to care. A common strategy employed in low-resource settings is to engage in task shifting or task sharing, where nonmental health specialists such as lay community members or traditional healers may be trained to outreach to communities to engage in stigma-reduction work, promote awareness through psychoeducation, deliver psychosocial intervention, or support access to psychiatric treatment. One successful example is the “Friendship Bench” project, where trained lay community health workers are stationed on benches in accessible places to deliver problem-solving therapy to alleviate kufungisisa, the symptom of “thinking too much,” in addressing the treatment gap for depression and anxiety in Zimbabwe. The intervention group led to greater improvements as measured by the SSQ-14 and PHQ-9 compared to standard psychiatric care enhanced with information, education, and support. Its success has also led to its implementation in New York City.

As the field develops, concerns have been raised that Western conceptions of mental disorders may dominate over other alternative concepts as a form of intellectual colonialism and epistemic injustice; diverse and unique cultural expressions of distress and pathways for healing may be ignored or endangered; interventions may be unduly influenced by pharmaceutical industries; social determinants of health and mental health may be ignored; and initiative agendas and gains may be coopted by Western researchers. These remain legitimate concerns that GMH clinicians and researchers need to be mindful of and reflect on.

In part in response to these criticisms, the most recent Lancet Commission on Global Mental Health report in 2018 broadens the GMH agenda in the context of the U.N. Sustainable Development Goals. The aim is to extend the agenda beyond decreasing the treatment gap to also include closing the quality gap and the prevention gap. It proposes four foundational pillars: (1) mental health is for the global public good and is relevant to all countries; (2) mental health exists in a continuum from distress to disorder to disability rather than a binary approach of diagnosable mental disorders; (3) the mental health of each person is a product of social and environmental influences interacting with genetic, neurodevelopmental, and psychological processes and affecting biologic brain pathways; and (4) mental health is a fundamental human right.

The reframed and broadened agenda entails six key actions: (1) mental health services need to be scaled up as an essential component of universal health coverage and integrated with other global health priorities; (2) barriers to mental health need to be addressed including stigma, climate change, and growing inequalities; (3) mental health needs to be protected by public policies and developmental efforts with intersectoral engagement of stakeholders within and beyond the health sector such as education, workplace, social welfare, criminal justice, child and youth services, humanitarian efforts, and others; (4) innovation need to be embraced, including the use of non-specialist individuals and digital technologies; (5) investments in mental health should be increased in view of the strong evidence of the intersection between economics and health; and (6) investments in research and innovation should be increased in diverse disciplines such as genomics, neuroscience, health services, clinical sciences, and social sciences both to promote discovery of causal mechanisms and research in implementation science.

Implementation science is the scientific study of methods to promote systemic uptake of evidence-based practices to enhance access to care as well as quality and effectiveness of care. It is often used as a framework to guide GMH research or initiatives. An example of a common implementation science framework is the RE-AIM framework, which includes: Reach, examining the number and characteristics of individuals who can or cannot participate in the initiative; Effectiveness, assessing the outcomes of the initiative; Adoption, gauging uptake at organizational and systemic levels; Implementation, examining the process of conducting the interventions in real-world settings, including the balance of local cultural adaptation and fidelity; and Maintenance, evaluating the enduring effects at individual and organizational levels. While being mindful of overarching project goals and ethical considerations, the key to applying the implementation science framework successfully in GMH contexts includes equitable collaboration with local partners and stakeholders; careful cultural adaptation of concepts and interventions; and flexible adjustment of project parameters to suit local needs and changing contexts.

The challenge of the grand mission of GMH, and indeed psychiatry, in alleviating human suffering remains daunting and its methods are not without pitfalls and criticisms. There may always be a tension between an “etic” perspective–an outsider, universalizing approach–versus an “emic” perspective–an insider, particularistic cultural approach. Rather than an either-or position, a dialectical approach is possible. The integration of cultural psychiatry into GMH and the field of psychiatry at large will lead to improved research, training, clinical practice, and ultimately, patient and societal outcomes.

4.3 Evolutionary Foundations for Psychiatric Research and Practice

RANDOLPH M. NESSE, M.D.

FIVE ADVANCES

Major advances in the evolutionary explanation of behavior and emotions from the second half of the 20th century have yet to be fully applied in psychiatry. This chapter summarizes those advances and how understanding them can make clinicians and researchers more effective. Some have direct applications, such as understanding the human mating system, how negative emotions are useful, and why there are no common alleles with large effects on highly heritable diseases such as schizophrenia. However, the big payoffs, in the long run, will come from the integrated framework evolution provides for understanding normal behavior and psychopathology. Evolutionary approaches are not an alternative to understanding mechanisms; they are the crucial complement that explains why mechanisms are the way they are and why they are vulnerable to failure. Evolutionary biology provides a framework that can transform the bio-psycho-social model from a catchphrase into a solid working model. It provides, for psychiatry, what physiology provides for the rest of medicine—an understanding of normal functioning as the foundation for understanding pathology.

Five major advances in evolutionary biology are especially important for psychiatry. Each is described briefly below.

Proximate and Evolutionary Explanations Are Both Essential

Until the middle of the 20th century, the study of animal behavior was mostly descriptive. Meticulous observations by ethologists described behavior in detail, but theory was absent. Everything changed in the mid-1960s, with the recognition that all biologic traits need evolutionary as well as proximate explanations. This insight came first from students of animal behavior, especially Niko Tinbergen. So-called “proximate questions” are about mechanisms; answers to such questions describe how mechanisms work and how they develop. Other “evolutionary questions” are about how traits got to be the way they are; answers to such questions describe how and why the trait changed over evolutionary time. For instance, a proximate explanation of anxiety describes the relevant brain and psychological mechanisms, how they develop, and how they are influenced by events and environmental influences. However, even describing every detail about the proximate mechanism does not explain why the capacity for anxiety exists at all. That requires an evolutionary explanation of how the capacity for anxiety increased fitness for our ancestors.

In a famous article published in 1963, Tinbergen outlined four questions that all must be answered to provide a complete understanding of any trait. Two are evolutionary questions. The first is about phylogeny, the history of a trait. The second is about the adaptive significance of the trait and what forces of selection shaped it. There are also two proximate questions. The first is about the mechanism and how it works at all levels, from molecules to social psychology. The second is about ontogeny, how the mechanism develops in an individual from a zygote to an adult (see Fig. 4.3–1). Almost all research in psychiatry has been to describe mechanisms, their development, and their malfunctions. Only now is attention turning to also address evolutionary questions, such as why emotions exist.

Behaviors Need an Evolutionary Explanation

The second core advance, closely related, was the application of evolutionary thinking to behavior. Initial approaches provided evolutionary explanations for specific behaviors, such as rams butting horns in the mating season and birds removing broken shells from nests to avoid attention from predators. It was soon recognized, however, that it was not behaviors themselves that natural selection shaped but behavior regulation mechanisms. That is, the brain.

A general core principle soon became clear: **brains are shaped by natural selection to give rise to behavior that maximizes Darwinian fitness**. Instead of implying rigid behavior patterns, this principle recognizes the enormous fitness benefits of flexible behaviors that allow organisms to adapt to rapidly changing situations. Learning is not an alternative to an evolutionary explanation. It is a capacity shaped by natural selection. Textbooks of animal behavior are now all grounded in evolutionary biology.

Social Behaviors Need Evolutionary Explanations

The evolutionary analysis of social behavior was central to transforming animal behavior research. The old idea that organisms are shaped to behave in ways that benefit their groups and species was replaced by a recognition that selection generally shapes traits that maximize individual fitness, even if that harms the group. Many have heard about lemmings jumping into the sea for the good of the group when food is too scarce for all to survive. This turns out to be a myth, one promulgated by a Disney film that seems to show lemmings flinging themselves off a cliff when in fact, they were swept off by workers with brooms. An allele that induces individuals to sacrifice themselves for the good of the group will be quickly selected out except in certain special circumstances. Behaviors costly to individuals that benefit groups, such as parents sacrificing for their offspring, wolves sparing those who signal defeat, or crowded populations reducing reproduction, have other explanations.

Tinbergen's Four Questions		Two Objects of Explanation	
		Diachronic The historical/developmental sequence that shaped the trait	**Synchronic (single form)** The trait at one slice in time
Two kinds of explanation	**Proximate** Describes the mechanism and its ontogeny	**Ontogeny** How does the trait develop in individuals?	**Machanism** What is the structure of the trait; how does it work?
	Evolutionary Describes the adaptive significance and phylogeny	**Phylogeny** What is the phylogeny of the trait?	**Adaptive significance** How have variations in the trait influenced fitness?

FIGURE 4.3–1. Tinbergen's Four Questions. (Adapted from Nesse RM. Tinbergen's four questions, organized: a response to Bateson and Laland. *Trends Ecol Evol*. 2013;28(12):681–682. Copyright © 2013, with permission from Elsevier. doi: 10.1016/j.tree.2013.10.008.)

Kin Selection Explains a Lot of Social Behavior

Recognition that costly individual sacrifices cannot routinely be explained by benefits to the group was followed closely by William Hamilton's discovery of the main exception, kin selection. Close relatives share genes that are identical by descent; 50% of a child's genes are identical to each of its parents. Alleles that decrease an individual's number of offspring can be selected for if they sufficiently benefit identical alleles in kin. Hamilton's famous formula, $C < B \times r$, is a crucial foundation for understanding family relationships. An action that costs an amount C can nonetheless give inclusive fitness benefits if C is less than the benefit to a relative, B, times the percentage of genes identical by descent. In the classic example, it is not worthwhile to sacrifice one's life for a sibling, but it is for two siblings or eight cousins. The term "inclusive fitness" incorporates the reproduction of an individual's relatives as well as the individual. Kin selection offers a profound evolutionary explanation for basic human behaviors, such as parents making sacrifices that benefit their children.

This discovery led to thinking in terms of “selfish genes.” The metaphor has been useful to combat naïve group-selection thinking, but it has been somewhat too potent for its own good. If genes are selfish, this seems to imply that organisms must be selfish. However, capacities for generosity and moral behavior exist because they increase inclusive fitness. Selfish genes make individuals who can be generous…selectively.

Evolutionary Medicine

Natural selection shapes traits that work well, so it would seem unable to explain diseases. That’s correct—diseases are not shaped by natural selection, and viewing diseases as adaptations is a serious but common mistake. However, traits that leave individuals vulnerable to disease, such as the appendix, the narrow birth canal, and the capacity for low mood, have been shaped by natural selection. Evolutionary medicine tries to understand, for each disease, why selection has left bodies vulnerable. Six main kinds of explanation help to organize the search. Notice that these are not explanations for why some individuals become ill while others do not. Instead, they are about why all humans share vulnerability to a disorder.

Six evolutionary explanations for vulnerability

1. Mismatch with modern environments
2. Constraints–things selection cannot do
3. Co-evolution with fast-evolving pathogens
4. Tradeoffs
5. Reproduction at a cost to health
6. Defenses that are useful but costly and aversive

Mismatch of the Environment to the Body. Most chronic disease results from the mismatch between our bodies and the modern environments we have created. Atherosclerosis, breast cancer, and autoimmune diseases are vastly more common in technological societies. So are obesity, eating disorders, alcoholism, and drug abuse. Our behavior regulation mechanisms were never shaped to cope with the ready availability of hamburgers, candy bars, whiskey, and heroin. Our distant ancestors also never had to cope with life in bureaucracies, 9-to-5 jobs, alarm clocks, and expectations of lifetime monogamous mating, they were, instead, responding to different, often harsher environments with different survival needs.

Many alleles that predispose to major disorders are not defects; they are merely “quirks” that cause harm only in modern environments. For instance, nearsightedness is highly heritable but nonetheless rare in hunter-gatherer populations not exposed to reading early in life. Other heritable tendencies may have vastly different significance in modern environments. For instance, a short attention span may not have posed serious problems for hunter-gatherers. Some who advocate an evolutionary approach to mental disorders have incorrectly attributed nearly all problems to a mismatch with modern environments; such factors are significant, but the five other factors are also important.

Pathogens Evolve Faster Than Hosts. Infectious disease will always be with us because pathogens evolve much faster than we can. Also, every time selection shapes a host defense, pathogens evolve some way around it. The resulting arms race leaves us with costly defense mechanisms prone to causing disease.

For instance, streptococci have evolved immune markers similar to human tissues, making it risky for our immune system to attack them. Rheumatic fever, Sydenham’s chorea, and some cases of obsessive-compulsive disorder are examples. Selection shapes immunologic defenses to high levels of aggressiveness, whose associated effects can cause mental disorders. For instance, inflammation now appears to cause some depression and most Alzheimer disease.

Constraints. There are many things that natural selection cannot do. It can never completely prevent mutations, although the extraordinary fidelity of DNA replication illustrates the power of selection. Evolution also cannot redesign a trait from scratch; it proceeds only by the process of small “tinkering” changes. So, while birth via the pelvis is painful and dangerous, no alternative route can evolve. Similarly, vertebrates are stuck with the blind spot where nerves and vessels enter in the back of the eyeball, while cephalopods have nerves that traverse their eyeballs without causing a blind spot. Some human cognitive biases and heuristics that limit objectivity result from the continuity of mechanisms shaped to make simpler decisions. Emotion regulation mechanisms likewise often fail because they are products of tinkering with preexisting mechanisms.

Tradeoffs. No trait can be perfect. The vast majority of changes that could make a trait superior in one respect would make it inferior in other respects or would compromise the effectiveness of other traits. Finches with larger beaks can crack tougher seeds, but they have less access to very fine seeds. Individuals with more tendency to anxiety are able to avoid dangers but at the cost of the inability to take advantage of many opportunities.

Reproduction at the Expense of Health. It is disturbing but essential to recognize that natural selection does not shape organisms to maximize health, happiness, or longevity. It instead maximizes inclusive fitness. Usually, health and long life are good for fitness. However, an allele that harms health will nonetheless spread if it increases reproduction.

The best example is the short lives of men compared to women. Male mortality rates in early adulthood are three times those for women in modern societies because tendencies that lead to success in the mating competition are selected for in males even if they harm health. Tendencies to tissue repair and sensible caution are relatively favored in females.

Much research has sought to understand the proximate mechanisms that account for women having more anxiety disorders than men. An evolutionary framework suggests that it is men who have the problem. Women have closer to the optimal amount of anxiety for their own health and well-being, while men tend to be reckless in ways that benefit their genes

Some have speculated that tendencies to mania may have been selected for because they result in increased matings and increased reproductive success. If that were really the case, then tendencies would spread and become universal. This provokes an interesting possible explanation for the high prevalence of cyclothymia. However, the rarity of manic depression suggests that the increased sexuality of individuals with tendencies to mania has not paid off with net increases in the number of grandchildren.

Defenses. Most problems people bring to their physicians are not direct manifestations of disease; they are useful defensive responses, such as pain, fever, cough, nausea, and vomiting. These defenses, shaped by natural selection, are usually expressed only in the presence of some problem or disease, but they are not diseases themselves. This knowledge is crucial for making good clinical decisions about when to block such defenses.

Understanding the smoke detector principle is also crucial for making such decisions well. Natural selection shapes mechanisms that express defenses, such as panic, whenever the benefits are greater than the costs. However, the presence of a threat is often uncertain, so even an optimal system will have some false alarms and some failures to respond when a response would be useful. This is particularly germane for understanding panic attacks. A fight–flight response will be potentially lifesaving if the noise from behind a rock is made by a lion, but it will be wasted if the noise is coming from a monkey. Whether an individual should flee depends on how likely it is that the noise was from a lion. If the cost of flight is, for instance, 100 kcal, and the cost of not fleeing if the lion is actually present is 100,000 kcal, then the optimal system will set off the fight–flight response whenever the noise is loud enough to indicate a probability of a predator being present of greater than one in 1,000. This means that 999 responses out of 1,000 will be false alarms, each useless but completely normal. False alarms in defense regulation systems are expected and normal. This has profound implications for understanding and treating not only panic disorder but also depression, pain, cough, and fever.

CORE PRINCIPLES OF EVOLUTIONARY BIOLOGY

Evolution has two major components, both discovered by Darwin. The first is the unity of all life; all individuals in all species are descendants of ancestors that go back in an unbroken chain to the origins of life on earth. This is phylogeny, now traceable via genomics. It is relevant for tracing human origins and for identifying the history of alleles related to mental disorders, but our focus here will be on Darwin's second discovery: natural selection and how it explains adaptations. It is the only viable explanation for why so many aspects of organisms are well-suited to coping with life's challenges. The rabbit's astute hearing, the woodpecker's barbed tongue, and the eagle's sharp eyes are products of natural selection. So are human empathy, emotions, cognition, capacity for language and love, and jealousy. Or, more exactly, the brain and its mechanisms for regulating thinking, emotions, and behavior.

Natural Selection

Natural selection is best understood in the context of selection in general. If members of a group differ in ways that influence their likelihood of being in the group in the future, the group will change over time. If you put all coins from your pocket into a jar each evening and select only the silver-colored coins in the morning, the jar will gradually take on a copper hue as the concentration of pennies increases. Television producers try out extraordinarily varied offerings. Those that get viewers and advertising dollars persist and are imitated; others are eliminated. Selection explains how groups change when variations among individuals influence their contributions to future groups.

Natural selection is the subtype of generic selection in which the variations are products of genetic variation that influence reproductive success. The principle is simple. If individuals in a population differ genetically in ways that influence how many surviving offspring they leave, the average characteristics of the population will change over the generations. This is not a theory; it is a theorem that is necessarily true. In the classic example, if previously light trees become covered with soot and moth color varies, light-colored months are more likely to be eaten by birds, so the average moth will become darker over succeeding generations. VISTA is a useful mnemonic for the process of natural selection: Variation, Inheritance, Selection, Time → Adaptation.

Dogs offer a familiar example. From their common ancestors in wolves, artificial selection has produced dramatically diverse dog breeds in just a few thousand years. The process of natural selection is the same as breeding, except that differences in offspring numbers result not from decisions made by breeders but from variations in the ability to cope with challenges that influence reproductive success. The products of natural selection look as if they were designed, and the sequence of species makes it seem as if there is something planned, or at least preordained, about the progression. However, there is no plan or endpoint, and traits that appear to be designed were shaped by mindless natural selection.

Standard examples usually describe how natural selection changes a trait. However, natural selection mostly keeps traits the same. If individuals 7 feet tall had more children than others, the mean height would shift to that optimum. If individuals more aggressive or outgoing than others consistently had more children, the population mean would shift. However, at least over the past few tens of thousands of years, individuals at the extremes of height, aggressiveness, and extroversion almost certainly had fewer offspring than those closer to the mean. The persisting wide variation in these traits suggests that fitness is similar across a wide range.

Whether a trait or a gene is advantageous or deleterious depends on the environment. In equatorial climates, dark skin protects against sun damage; in cloudy environments, it can result in rickets from insufficient sunlight-induced vitamin D synthesis. A tendency to prefer fatty foods can be useful where fat is scarce, but in modern environments, it can lead to disease.

Evolution

Evolution involves much more than natural selection. The three other main forces are mutation, migration, and genetic drift. **Mutations** happen despite being minimized to an astounding degree by natural selection; increasing evidence points to their importance in explaining schizophrenia, autism, and bipolar disorder. **Migration** may strongly influence the prevalence of an allele in a population. Most northern Europeans can digest milk because migrants brought the relevant gene from rapidly expanding dairying populations further south. Huntington’s chorea is especially common near Lake Maracaibo in Venezuela because Antonio Justo Doria, a Spanish sailor, brought the mutation there in the late 1800s. **Genetic drift** refers to changes in gene frequency, more correctly allele frequency, that result from random factors. An allele that increases fitness may be lost from an entire population if the individuals carrying it all die in an accident. An allele that is mildly harmful can nonetheless become more common if those who carry it have more children than others just by chance. Alleles whose effects on fitness are close to neutral can drift to fixation or be eliminated, especially in small populations. There are good reasons why population genetics relies on the so-called “null model,” in which frequency changes result only from drift. This is not, however, an alternative to natural selection or a reason to think that most traits are not well-suited to their functions.

What Selection Shapes

The usual textbook examples of selection are fixed physical traits such as bird beaks and moth wing color. Far more important for psychiatry, however, is selection of systems that regulate the body and behavior.

Most regulation systems keep things stable. Selection shapes mechanisms to maintain homeostasis at every level. Regulation of glucose, oxygen tension, acid–base balance, and osmolality are the usual examples.

The association of natural selection with fixed traits and systems that maintain homeostasis fosters the misperception that an evolutionary explanation somehow implies rigidity, especially rigidity of behavior. Nothing could be further from the truth. Natural selection has shaped hundreds of mechanisms that adjust organisms to changing situations. The traits vary in scale from the molecular to large-scale behavior, and across time from instantaneous changes to those that play out over a lifetime. The term *plasticity* often refers to longer-term changes, especially those that shape an individual in relatively irreversible ways as function of early experience, such as the barrel-shaped chest of humans living at high altitudes. In the medium term, high altitude increases hemoglobin concentration, and exposure to sunlight induces skin tanning. In the short term, cold induces shivering, infection causes fever, and threat arouses fear. Some responses, such as blinking, are nearly instantaneous. All are facultative adaptations, mechanisms shaped by selection that adjust phenotypes to changing aspects of environments.

The brain is obviously responsible for many such responses. It monitors internal and external cues as input to mechanisms that adjust physiology, expression, behavior, cognition, and more. These responses vary across individuals, and some of the variation results from genetic variation. To make a long story short, the brain was, like every other organ, shaped by natural selection. We know what it is for. It regulates behavior and other responses in ways that maximize inclusive fitness. Capacities for learning and relationships are especially valuable ways to accomplish that. Humans have, perhaps uniquely among all animals, capacities for abstract representation that make language and causal thinking possible. We also have distinctive capacities for enduring relationships that go beyond merely trading favors. These capacities, in turn, make possible social complexities and cultures that create new selection forces that further shape brains in a feedback process that has shaped our astounding social and cognitive abilities. An evolutionary approach to human nature emphasizes the remarkable plasticity and adaptability of behavior to different circumstances.

An example of potential importance for psychiatry is the possibility that selection has shaped a mechanism that detects and responds to early adversity by shifting development to create phenotypes that can cope with an anticipated short lifespan in a harsh environment. This could help account for the increased risk-taking, stress sensitivity, and inflammation and resulting chronic diseases that are more common in children who were abused early in life. However, it is hard to exclude the possibility that the associations arise from confounding genetic, environmental, or social factors or from individuals simply making good decisions in bad environments.

Genotypes and Phenotypes

Natural selection changes gene frequencies, more accurately, frequencies of specific alleles and other genetic variations. Population genetics describes how selection, migration, and genetic drift increase and decrease allele frequencies in different situations. This sometimes gives the impression that evolutionary explanations are genetic explanations, and that gives the impression that an evolutionary approach to behavior somehow implies a commitment to genetic explanations for variations in personality and behavior. These are misconceptions. It’s instructive to realize that Darwin knew nothing about genes. The principles of natural selection were discovered by observing variations in phenotypes.

Genes carry the information that is acted on by natural selection, but that action is almost entirely via interactions of phenotypes and environments. Just as the adaptive value of a trait depends on the environment, there is no such thing as an allele that is useful in general; the adaptive significance of a genetic variation depends on its interactions with other genes (epistasis) and interactions with environments.

Sexual Selection

The interests of individuals and their genes are generally the same. An allele that makes healthy long-lived phenotypes is more likely to be passed on. There is, however, an exception. Mutations that decrease health, happiness, longevity, or cooperativeness will spread if they increase the number of offspring.

Sexual selection is the best example. It is the subtype of natural selection in which individuals compete for mates, either by displaying extreme traits that lead to being chosen by the other sex, or by traits that lead to success in competing with others of the same sex. Gigantic colorful tails are a costly drag for peacocks, but the responsible genes spread because peahens prefer peacocks with big tails. The process can set up a positive feedback loop in which the advantages of extreme male traits give advantages to female preferences for those traits because sons with extreme traits will have an advantage. The trait becomes more extreme until the costs it imposes are as large as the reproductive benefits.

The relevance of sexual selection to humans is illustrated by the excess mortality rates experienced by men compared to women. In the early reproductive years in modern societies, as mentioned above, men in the early reproductive years are three times more likely to die than women. Much of the excess is from fights and accidents, but almost all causes of death are greater for males because they allocate effort to competitive ability at the expense of tissue repair. Even early childhood mortality rates are 50% higher for boys than girls.

Sexual selection is a subtype of social selection, the more general category of evolutionary change resulting from social choices and competitions. In sexual selection, the resource at stake is mates, with its obvious connection to reproductive success. However, especially for humans, competition for status, friends, and group memberships also influences reproductive success. Individuals preferred as relationship partners or group members get advantages substantial enough to shape extreme human capacities for altruism and empathy unmatched by any other species. These advantages also help to account for extraordinary social sensitivity and the prevalence of social anxiety in humans.

Many people experience extreme concern about what others think about them. One possible explanation is that other people’s opinions can help or harm reproductive success. There are good evolutionary reasons why many psychiatric disorders are associated with internalizing or externalizing personality extremes. There are good evolutionary reasons to expect constant conflicts between (id) impulses to get short-term advantages and (superego) constraints that sacrifice personal short-term gain for longer-term benefits of being a preferred social partner. Rigidity that emphasizes one over the other is disadvantageous and is recognized as sociopathy or neurosis, respectively. Most people benefit from mechanisms shaped by selection that allow them to shift their social strategies as a function of subtle shifts in social circumstances.

Levels of Selection

Recognition that selection works mainly at the level of the gene and the individual has profound implications for psychiatry. While few evolutionary biologists now support the idea that traits are routinely selected to benefit the group or the species, debates about levels of selection persist, and the idea of group selection remains attractive to many nonbiologists. This may be, in part, because it is so often framed as an explanation for “the mystery of altruism.” Genetic variations that induce costly helping of nonrelatives will become less common in each generation, even if the group benefits. But such tendencies exist, thus posing the mystery. As noted already, kin selection solves the mystery when group members are relatives. But how can we explain examples of cooperation between non-kin? Many examples are “mutualisms” that give benefits to both parties with no opportunity for defection, such as two people moving a heavy rock to get food. Often, however, exchanges are not immediate, leaving the possibility that one partner will fail to reciprocate a favor. Such “reciprocity” exchanges have been subject to exhaustive modeling using the prisoner’s dilemma schema. In this model, the largest payoff goes to an actor who defects when the other person cooperates. If both cooperate, they both get a modest benefit. If both defect, neither gets any benefit.

Because the cells in an individual’s body are all genetically identical, their interests are almost always aligned with the welfare of the individual. The machinations of meiosis ensure that only a single copy of each chromosome gets into a gamete, preventing otherwise destructive genetic competition. Metazoans also have manifold mechanisms to suppress lack of cooperation, such as apoptosis which eliminates cells that start dividing out of control. It is possible to view those mechanisms as shaped to benefit the whole organism, and they certainly do, but the genes that mediate such enforcement persist because of benefits to themselves that result from benefit to the individual.

Some exceptions to genetic cooperation are particularly important for psychiatry. In particular, the interests of maternal and paternal genomes differ. Female mammals invest a proportion of their available resources in a pregnancy, reserving some for future offspring. The male parent may or may not be the parent of those future offspring, so the paternal genome gets an advantage if the fetus extracts a bit more nutrition from the mother. It may seem preposterous that maternal and paternal genomes should compete over relatively small differences in investment in an infant, yet intriguing genetic evidence suggests this is exactly what is happening.

IGF-II alleles tend to make offspring bigger. When they are passed on via an egg, they are imprinted, that is, methylated in a way that inhibits expression of the gene, thus making the baby smaller. IGF-IIr alleles counteract the actions of IGF-II, yielding larger offspring. IGF-IIr alleles are imprinted if they come through the paternal line. The balance between these opposing forces yields babies of normal size, but if imprinting is missing for either gene, offspring will be especially small or large.

It has been suggested by Bernard Crespi and colleagues that this phenomenon may be related to schizophrenia and autism. They can be speculatively viewed as flip sides of the same coin, with autism reflecting unbridled influences of the paternal genome, and schizophrenia reflecting excess influences of the maternal genome. Genes that increase the risk of schizophrenia and autism are imprinted in ways remarkably congruent with this theory. A recent study found, as predicted, that babies lighter than average were especially likely to develop schizophrenia, while those born heavier than average were more likely to develop autism. These findings support but do not confirm the theory, and large-scale genetic studies suggest that the issue is much more complex than can be described here, but Crespi’s suggestion is an illustration of how we might test a creative idea inspired by evolutionary thinking.

A more mundane but nonetheless fascinating example is the weaning conflict. There is a period when mammal mothers try to stop nursing, but infants protest vigorously and try to continue. This conflict is predictable from evolutionary principles. The mother and infant share 50% of their genes, but the infant shares 100% of its genes with itself. A mother that fails to nurse her infant loses a huge investment, so providing whatever her baby needs early in life is in the mother’s genes interests. As the baby grows, it is increasingly able to get nutrition from other sources. At some point, this means that the mother’s reproductive success would best be served by another pregnancy. The baby’s interests, however, are best served by continuing to nurse until the point when the benefits via kin selection to a younger sibling (who shares 50% of genes) are as great as the benefits from continuing to nurse. At this point cessation of nursing is in the child’s interest, so the weaning conflict ceases. An extensive literature in psychoanalysis and child development investigates nursing and weaning, but much remains to be done to put it in an evolutionary context.

Misunderstandings About Natural Selection

Some common misunderstandings about evolution deserve mention. Is evolution over for humans? No. Even if all individuals in a species live for the same number of years, natural selection will change the average characteristics of a species if heritable traits influence numbers of offspring. This does not meet that future traits can be predicted with certainty. Death from drunk driving is now a powerful selection force, but it is hard to say whether it will select for disliking alcohol or better driving while drunk.

Can selection have any impact after menopause? Many people think not, but this is because they have not recognized the role of kin selection. Postmenopausal women have a major influence on the proportion of their genes in future generations when they do things that help their grandchildren. Eric Erickson's generative phase of life has an easy evolutionary explanation. It remains uncertain if menopause is an adaptation shaped by the advantages of taking care of existing children instead of undergoing the risks of reproduction at an advanced age that might jeopardize the welfare of existing children.

Do we all have Stone Age bodies and minds, unchanged for the past 10,000 years? No. Substantial changes have been documented; examples include changes in skin color, ability to digest lactase, and the ability of certain human subpopulations to cope with high altitudes. Increasingly complex social structures may also have imposed strong selection forces that have shaped social and emotional traits and language abilities. Selection for behavioral traits may have sped up since the development of agriculture changed human social structures.

The opposite misconception, that selection changes traits in just a few generations, is also prevalent. However, selection is too slow to adjust our bodies to environments that change drastically over just a few generations. Some people think that nearsightedness, a highly heritable trait, has become more common because the invention of eyeglasses has made it less of a disadvantage. However, a few hundred years is not nearly enough time for disadvantageous alleles to drift to a prevalence that would cause disability in about a third of the population. Myopia is a fine example of a "genetic quirk." The responsible alleles probably have disadvantageous consequences only when they interact with some modern environmental factor, possibly early reading, to cause pathology. One wonders how many alleles that predispose individuals to psychiatric disorders are also not defects, but quirks.

Does an evolutionary view of behavior imply some kind of rigidity or genetic determinism? As noted already above, but deserving repetition, natural selection has shaped learning and innumerable other mechanisms that adapt bodies to changing circumstances. Like learning, culture is not an alternative to an evolutionary explanation. Natural selection has shaped a capacity for culture that unleashed new selection forces that have given humans social capacities unmatched by any other species. Gene-culture coevolution escalates human capacities for culture, which in turn makes a more complex culture possible, in a positive feedback cycle whose end is not yet in sight.

Much difficulty incorporating evolutionary biology as a basic science for psychiatry arises because of perceptions that it is associated with atheism. While belief in God is less common among scientists compared to the general public, the fact that humans have been shaped by natural selection does not directly imply anything about the existence of God. It does contradict some myths that are interpreted literally by some religious traditions, however many religions, including the Catholic Church, now officially recognize that humans are products of natural selection.

BEHAVIORAL ECOLOGY

The synthesis of ethology with evolutionary biology produced the field now known as behavioral ecology. It analyzes how behavior patterns influence fitness. Aside from the core principle that behavior tends to maximize inclusive fitness, behavioral ecology focuses on trade-offs between the different kinds of efforts individuals exert to get different kinds of resources. It routinely distinguishes several categories of effort. Somatic effort is to get calories and other resources to grow, sustain, and protect the body. Reproductive effort is to get mates and take care of offspring. Social effort is to recruit allies and to achieve status in the group.

This framework offers a powerful tool clinicians can use to unpack the sources of stress. Just as physicians conduct a Review of Systems to consider all possible sources of a problem, mental health clinicians need to conduct a Review of Social Systems to consider all possible sources of emotional problems. Most stress comes from the inability to get a secure, sufficient supply of some resource, a threat of loss of a resource, or because efforts to get one resource interfere with efforts to get another. Examples abound in the clinic. One person may be working 70 hours a week, and feeling, correctly, that this makes searching for a romantic partner unrealistic. Another may be stressed because a commitment to full-time childcare makes it hard to allocate effort to anything else. Many people are distressed because of inability to find a mate, infertility, insecurity of a marriage, or wanting to leave a relationship. Many others are unable to find a satisfactory job, worried about losing a job, or feeling stuck in a position that provides little respect.

Other problems arise from unbalanced allocations of effort. For some people money is the overwhelming goal, others are dedicated to being good, getting famous, having friends, or taking care of children. The task of balancing efforts to get these various resources is constant, and imbalances create pathology. Narcissism can be viewed as investing all life effort in the pursuit of self and status to the exclusion of all else. Conversely, some patients invest all effort into trying to please others. Some are preoccupied with their appearance, others with their wealth. Stress often arises from health problems that make it impossible to pursue other goals.

Review of S.O.C.I.A.L Systems

Social status, friends, and groups
Occupation and other valued social roles
Children and family
Income and material resources
Abilities, appearance, health, and other personal resources
Love and sex

To identify the specific source of life stress, one can ask, for each area, what the person has, wants, is trying to do, expects, and the person’s feelings about how things are going in that area. No one ever has everything they want securely and to full measure, but it is nonetheless useful to distinguish at least three groups: patients who have generally adequate sources for most of life’s core resources, patients who lack or have lost something crucial or are facing a threat, and patients those who lack sources of most main life resources.

Other animals face the similar challenges. A grazing white-tailed deer looks up from the grass every few minutes to see if enemies might be present. Each time the animal looks up, it takes time away from eating. The allocation of effort between foraging and defense is regulated according to the level of nutritional supplies and the danger from predators. Risk-taking is also adjusted according to circumstances. Birds given a choice between a feeder that provides one seed every visit, and one that provides six seeds every sixth visit, generally prefer the steady payoff. If, however, the temperature is lowered to a point where the steady payoff provides too few calories to survive through the night, they switch to the risky payoff because that at least offers some chance of survival.

Studies of foraging also have important implications for psychiatry. Food for most animals is distributed in patches, such as different fruit trees. Starting in a new patch often provides many calories per minute, but as the patch is depleted, payoffs slow. How quickly should the animal move to the next patch? It depends on how long it will take to find a new one. Staying too long will waste time, resulting in very few calories per minute. Moving too quickly to a new patch will waste time looking for food when it could be spent gathering food. The optimum strategy is to continue in the current patch until the rate of return declines to that averaged over many patches. This is Charnov marginal value theorem. Animals do not have to do calculus to figure out the optimum moving time; their brains have been shaped by selection to optimize such choices to a remarkable degree. This is relevant for attention disorders and for mood. Consider the enthusiasm experienced upon first beginning to pick berries from a new bush, starting a new job, or engaging in a new relationship. Inevitably, payoffs decline with time. Deciding when to make a change is a difficult decision that often is the focus of psychotherapy.

Reproductive Effort

Brains result in behaviors that maximize inclusive fitness, a term that combines the reproductive success of an individual and their relatives. The simplest rule of thumb is that natural selection shapes brains that result in behavior that tended, in ancestral environments, to maximize the number of grandchildren, nieces, and nephews.

This makes it seem as if everything depends on mating often and with many partners. Differences in reproduction are indeed evolution's engine, but the notion that reproductive success is maximized by maximizing mating success is simplistic. Compared to chimpanzees, humans have a remarkable ability to selectively inhibit sexual impulses. This ability must have given a selective advantage in the context of the mating patterns that developed during human evolution.

Sex and mating behaviors have been a natural focus of behavioral ecologic study. There is no room here to expand on this topic, but it is important to recognize that the very existence of sex poses an evolutionary mystery because parthenogenetic populations grow twice as fast as sexual ones. Also important are the forces that shape many small gametes in one sex (e.g., sperm) and fewer larger ones in the other sex (e.g., ova). This is the essence of the difference between males and females. It means that different mating strategies maximize fitness for males as compared to females. Compared to males, female mammals invest much more in each offspring—many calories and the time and effort of pregnancy—so the total number of possible offspring is quite limited. The investment of a male can be as little as a few sperm and a few minutes, so one man can have hundreds of children, an outcome uncommon in technologic cultures, but reported in cultures where agricultural surpluses made it possible for one man to have many mates. Variation in reproductive success is therefore potentially much larger for men; while some have many offspring, others have none.

However, the human mating system is quite different from that of most other primates. In particular, men make major investments in rearing children. In this respect, humans are more like birds than most other mammals in that rearing offspring takes two parents. Chicks left alone in the nest without protection are likely to quickly be eaten by a predator, so a partnership is required for successfully rearing young. Human babies are so helpless, and their rearing takes so many years, that just having sex was rarely enough to successfully reproduce.

Large investments in child-rearing make sense for a man only if he can be relatively certain that the children are his own. So, tendencies to jealousy and mate-guarding are human universals, although the range of accepted behaviors varies enormously between cultures, from death by stoning for what would elsewhere be dismissed as mere flirtation, to extramarital sex being widely accepted.

These distinctive aspects of the human niche are likely related to another human peculiarity—human ovulation is concealed instead of being advertised, as it is in many other primates. This may have increased paternity certainty by drastically lowering the benefits of forced copulation by a man who is not the woman's mate.

These generalizations are too often pushed to an essentialized version that purports to be THE normal human mating pattern, despite massive evidence for huge cultural variations in mating and family structures. Nonetheless, understanding the evolutionary origins of the human niche can be helpful in understanding marital conflicts, jealousy, and the complications of affairs and divorce.

Life History Traits

Traits such as the duration of gestation, rate of growth, age at maturity, interbirth interval, duration of nursing, and rates of aging are all shaped by selection. One particularly important dimension has been called fast-life versus slow-life strategy. In environments where life is short, reproductive success is maximized by taking risks and reproducing early and often, investing less in each offspring. In more secure environments, it is better to invest more in longer-term strategies and invest more in each offspring. The wide range of human variation on this dimension has been proposed to result from a facultative mechanism that responds to different environments by inducing a faster or slower life history strategy.

Attachment

John Bowlby's recognition of the adaptive value of mother-infant attachment marked the beginning of evolutionary approaches to psychiatry. However, he worked before the major advances that revolutionized the study of behavior, so it is not surprising that he and his followers have tended to see secure attachment as the norm, and other kinds as pathologic. Secure attachment is best for mental health, but important recent work has suggested that anxious or avoidant attachment may give selective advantages in some situations.

EMOTIONS

Emotions are special modes of operation shaped by selection to cope with the challenges that arise in situations that have recurred for thousands of years. Like sweating, cough, and pain, they are facultative adaptations that are useful in certain situations. They evolve in concert with mechanisms that monitor for cues associated with the situations in which they are useful. Like all such responses, emotional responses can be pathologically excessive or deficient. Determining if an emotional response is abnormal requires knowing the situation it has been shaped to cope with, and whether or not that situation is present.

When a patient presents with pain, fever, or cough, clinicians search for what might be arousing the response, such as tissue damage, infection, or foreign material in the lungs. When a patient presents with a negative emotion, the same kind of investigation is needed, but the search is more difficult. Instead of being aroused by tissue pathology or infection, emotions are aroused by less tangible situations. Modern emotions theory emphasizes that the associated stimuli are not just cues; emotions arise from an individual's appraisal of what new information means for their ability to pursue personal goals. A thorough investigation of the context is essential to determine if an emotion is normal and useful, normal but useless, excessive, or deficient.

Excesses of depression and anxiety are by far the most common mental disorders. Almost all effort to understand them has focused on what is different about people who experience intense anxiety or low mood, compared with other people. An evolutionary framework suggests different questions. Why do the capacities for anxiety and low mood exist at all? In what situations are they useful? Why are the mechanisms that regulate them so vulnerable to failure?

The most fundamental question is why emotions exist at all. Controversies about emotions distract from a growing consensus that they are special states shaped by natural selection along with regulation mechanisms that express an emotion in the situation where it gives a selective advantage. No one aspect of emotions is primary. Emotional states shift sensation, perception, cognition, behavior, physiology, motivation, and learning. Subjective experience is just one of many aspects of an emotion.

Controversy about emotion has focused on whether they are best viewed as distinct categories (the basic emotions view), or whether they are best understood as positions on dimensions, such as positive versus negative, and aroused versus calm. Neither perspective is consistent with the evolutionary origins of emotions. Emotions are neither fully separate nor fully dimensional; they are overlapping clusters of changes that have evolved from previous emotions (Fig. 4.3–2).

Some attempts to understand the utility of emotions have tried to map specific functions to specific emotions. However, most emotions serve multiple functions including motivation, communication, and changes in physiology and behavior. Emotions were not shaped to serve specific functions; they were shaped to improve coping with the challenges that arise in a **situation** that has recurred over evolutionary time. Being chased by a predator happened often enough that it reliably evokes a coordinated suite of physiologic behavioral and emotional changes, the fight–flight response. Realizing one has broken a promise arouses guilt. Experiencing generous help arouses gratitude. The key to understanding an emotion is to understand the situation it was shaped for.

One profound implication for psychiatry is that negative emotions are useful. Their aversiveness is one aspect that contributes to their utility. Anxiety, low mood, jealousy, anger, and envy exist because our ancestors with a capacity for these emotions got a selective advantage compared with those who lacked them. Negative emotions seem pathological because they are usually associated with untoward circumstances, and because they are so painful and prone to interfere with important daily tasks. However, they exist only because they have been useful… for our genes, if not for ourselves.

A Phylogeny of Emotions
R. Nesse 2004

FIGURE 4.3–2. A phylogeny of emotions. (Reprinted with permission from The Royal Society. Nesse RM. Natural selection and the elusiveness of happiness. *Phil Trans R Soc Lond.* 2004;359(1449):1333–1347. doi: 10.1098/rstb.2004.1511.)

Fear is useful in the face of threat. It mobilizes energy, cognition, and behavior to escape the danger. Like all facultative adaptations, pathology results from deficiencies as well as excesses. People with apparently excessive anxiety crowd our clinics. People with deficiency of the fear response, hypophobia, cope poorly with dangerous situations, but they rarely come for treatment.

Anxiety is often distinguished from fear because it is aroused by less tangible dangers that are distant or social. It is especially prone to be aroused by situations in which an individual is tempted to do something that might give a short-term advantage at a major social cost. Here too, pathology from excessive anxiety, especially social anxiety, is obvious, while the costs of anxiety deficiencies are far less obvious, even though sometimes more devastating. People with social anxiety tend to seek treatment, those with deficient social sensitivity suffer major social losses.

The value of low mood is much less obvious. The term *low mood* allows a description of states of low motivation, low self-esteem, and pessimism without the terminologic tangles that accompany the word “depression.” In what situation can sadness or low mood be useful? Sadness is aroused by a loss. It helps to recover, replace, or otherwise adjust to a loss. Low mood is aroused when efforts to reach a goal are proving fruitless. That situation has recurred millions of times for individuals in the course of human evolution. While simply persisting with a positive attitude seems intuitively attractive, that is not the best strategy when foraging in winter, trapped in the pursuit of an uninterested partner, or trying for the fifth year in a row to get into medical school. In such situations, it is best to pause, conserve energy, consider other strategies, and, if no route appears viable after all options have been explored, give up and put energies toward a more achievable goal.

Continued pursuit of an unreachable goal can escalate low mood into clinical depression. There are many possible reasons for inability to give up a goal. Few parents are able to give up trying to get a child off of drugs or alcohol. Many individuals have identities so grounded in their careers that they persist despite years of failure. And often, in the face of impending divorce, one partner persists in trying to preserve the relationship, even as demoralization turns into depression.

Other hypotheses about the origins of capacities for depression are also under consideration, many of which refer not to a situation, but to one specific function of depression. One is that depressive rumination pulls effort away from life pursuits so it can be allocated to finding solutions to complex social problems; analyses find little evidence that rumination actually leads to problem solutions. Another is that depression motivates looking inward at what one can do to avoid being expelled from a group.

Another is that depression symptoms give benefits by manipulating others. A particularly influential and plausible proposal is summarized in the phrase “involuntary yielding.” After losing a status competition, persisting in challenging the winner will likely bring more attacks or expulsion from the group. Experiencing oneself as helpless and even lower status than one actually is can prevent such attacks. The relevant situation is pursuing an unreachable goal in the domain of status competition. Subtypes of low mood have been shaped to cope with the different kinds of problems that arise in the pursuit of different kinds of goals. But a general understanding of the evolutionary origins of the capacity for mood variation based on how those variations can help to cope in situations that vary in propitiousness can help to forestall fruitless debates about which function of depression is most important.

Jealousy is aroused by a threat of the loss of a mate or the mate’s fidelity. Responsible for vast interpersonal problems and millions of murders, sexual jealousy is a toxic emotion. However, the situation of a mating relationship being threatened by an outsider has occurred so often over human evolutionary history, with such extreme effects on reproductive success, that it has shaped a specialized pattern of responses. The characteristics of jealousy are often unreasonable in the extreme, but game theory tells us that unpredictability is essential to a successful strategy. Being predictable means being manipulable. Not being fully aware of one’s motives or able to control one’s behavior may well be advantageous. Once again, the benefits may be for one’s genes, not necessarily for oneself.

Positive emotions are equally useful, even if not, unfortunately, so common. In situations characterized by short-term opportunities, it is valuable to experience enthusiasm, risk-taking, and energetic initiative. This suggests the counter-intuitive prediction that short-term opportunities will give rise to more enthusiasm and effort than long-term opportunities. Excesses of positive mood rarely motivate treatment-seeking except when they go to the extremes found in mania.

The resources that influence human reproductive success are overwhelmingly social, so we should expect to see specific emotions shaped to cope with the situations that arise in relationships. The boxes of the prisoner’s dilemma lend themselves well to understanding the origins of some social emotions. The game is named for situations in which the police offer leniency to whichever of two suspects first confesses the details of a crime. The dilemma arises because keeping quiet results in a modest punishment, but each prisoner knows that he will get a higher sentence if the other confesses first in order to get a lesser punishment.

Table 4.3–1.
Emotions Aroused by Situations that Emerge in Reciprocity Relationships

Social Emotions	Other Cooperates	Other Defects
You cooperate	Friendship, trust	Suspicion (before) Anger (after)
You defect	Anxiety (before) Guilt (after)	Rejection, disgust

Repeated cooperation by both parties arouses friendship, loyalty, and trust. If you cooperate when the other defects, anger is the reliable result. It signals that apologies and reparations are required to preserve the relationship. It also may be accompanied by spite, motivations to harm the defector even when the costs are larger for the self. This apparently senseless emotion gives selective advantages by its powerful ability to keep others from defecting when they otherwise would. The game-theoretic best strategy of doing what the other person did on the previous move is called tit-for-tat. It accounts for the runs of cooperation and defection seen in relationships (Table 4.3–1).

RELATIONSHIPS

Views of human relationships as fully explained by kinship and reciprocity are grossly simplistic. A small research industry has grown up to try to explain apparent anomalies of human social behavior, including tendencies to cooperation even without a guarantee of payback, willingness to punish defectors even when that will harm the actor, and eagerness for spiteful revenge that can have no direct payoff.

A key to such anomalies is found in a variation on the core principle. Just as selection shapes bodies to maximize reproductive success, even at a cost to health or longevity, it shapes minds and emotions to maximize reproductive success at the expense of rationality. As Robert Trivers pointed out in his preface to *The Selfish Gene*, the idea that selection shaped us for objective thought is naïve indeed. Often, especially in social situations, commitments beyond justification, and wishes for revenge beyond measure, are more useful.

This has an important implication for psychoanalysis and psychotherapy in general. While self-knowledge is desirable and can be enormously helpful, a lack of conscious access to one’s own motives and emotions may sometimes be adaptive. It has been suggested that the human capacity for psychodynamic defenses that maintain active repression of memories and motives may give selective advantages, not just by making life more bearable but also by influencing others.

The fields of sociobiology and evolutionary psychology study how natural selection shapes social behaviors and resulting group behaviors. There is no room here to explore the full framework. However, when a relationship is at the root of a clinical problem, as is often the case, a formal analysis of how that relationship is or is not working offers a solid starting place. This is very different from trying to understand the personality traits of the participants or the early events that lead to distortions and rigid relationship strategies. Instead, it looks at the history and current state of exchanges and expectations in the relationship.

While this perspective is just beginning to be applied, some clinical phenomena are readily approached from this point of view. For instance, the classic borderline personality pattern of excessive immediate intimacy and adulation, followed by disappointment and distancing, reflects a rigid relationship strategy of intense personal commitment that, when not reciprocated, leads to rejection and anger. The pattern in neurosis is more one of trying always to please others and being angry when they do not live up to expectations.

EXPLAINING VULNERABILITY TO SPECIFIC DISORDERS

As already noted above, every medical disorder needs two kinds of explanation. First, a proximate explanation for what aspect of the body’s mechanism has gone awry and why. Second, an evolutionary explanation for why natural selection has left the body vulnerable to this kind of failure. The six categories from evolutionary medicine help to explain vulnerability to mental disorders, just as they do to other medical disorders.

Disorders of Emotions

Determining whether a particular emotion is normal or abnormal requires understanding the situation in which that emotion is useful, the cues that usually regulate it, and the presence or absence of those cues. Current DSM diagnostic criteria ignore context and attend only to the frequency, severity, and duration of emotional symptoms. This works well at the extremes and increases diagnostic reliability but gives no guidance for cases where it is hard to decide if an emotion is normal or not.

The main evolutionary explanation for negative emotions is that they are useful defenses, with false alarms and excessive expression being common because of the smoke detector principle. Recognizing the utility of negative emotions should not inhibit attempts to relieve them. The rest of medicine routinely provides relief from normal pain, fever, and cough. Psychiatrists should relieve normal anxiety, low mood, and jealousy when that can be done safely. However, good decisions require an understanding of normal function.

> A professional motorcycle racer requested treatment because he was unable to sleep or keep food down the night before a race. The problem started when a friend died in a crash. It became worse after another crash caused another friend to become quadriplegic. He denied symptoms of other disorders and denied any problems with anxiety before his friend’s crashes. He had predictable difficulty recognizing the potentially life-saving nature of his anxiety.

Bad Feelings Are Usually Useless But Normal. It seems intuitively obvious that normal expressions of emotion should almost always be useful, and useless expressions should be products of some abnormality. This has spurred huge searches for neural and psychological abnormalities that cause anxiety and depression. Some instances are indeed products of defective regulation mechanisms. But an evolutionary perspective suggests that useless anxiety and depression usually arise from normal regulation mechanisms.

The smoke detector principle accounts for many instances. Many more arise from novel environments that arouse normal but useless emotions, such as despair from being trapped in a hierarchical bureaucracy or an inescapable marriage. Many bad feelings are harmful to the individual but good for their genes. Examples include sexual desires that cannot be satisfied, jealousy, envy, wishes for revenge, and blind ambitions that cause constant dissatisfaction. Finally, there are simple stochastic variations in an experience that result in normal but useless anxiety and depression. An unlucky sequence of failures sets a pessimistic schema in place that inhibits exploring the full landscape. Threat monitoring mechanisms adjust adaptively to increased sensitivity when repeated exposure to danger indicates they have not been doing their job. But that adaptive feature can easily slip into a positive feedback mode in which every experience of an emotion makes it more likely in the future. Panic disorder is the exemplar in which fear of panic attacks themselves sensitizes the mechanism further. Understanding and describing this vicious cycle for patients can be enormously helpful in itself, and it encourages completing difficult behavior therapy exercises.

Recognition that useless bad feelings often arise from normal mechanisms is a missing foundation for understanding emotional disorders. It helps patients escape from the identity of diseased persons and reframes symptoms as adaptive responses that are out of control. It helps clinicians to identify the root cause of emotional problems.

Schizophrenia

Most of the variation in risk for schizophrenia results from genetic variation. Why didn’t natural selection eliminate the responsible alleles? Many authors have suggested possible advantages to those with the disorder or, more plausibly, to their relatives. However, reproductive success for people with schizophrenia is a fraction of that for other people, and there is no documented advantage for relatives; this hypothesis fails. Others have suggested that it is a disease of modern environments. There are some small differences between cultures, but there is no evidence for dramatically lower rates in nonindustrial societies. New genetic evidence finds that every identified common allele that increases schizophrenia risk has only a tiny effect. Larger effects are mostly due to rare copy-number variations. This pattern is exactly what one would expect if selection were continuously and efficiently purging vulnerability alleles from the genome. Increased rates of schizophrenia associated with older paternal age suggested that de novo mutations might be major factors. They contribute but not that much; most of the association with the father’s age turns out to arise because men with genes that predispose their children to schizophrenia marry and have their first children later than other men.

The big unanswered question is why the cognitive system is so vulnerable to this particular kind of failure. One possibility is that some advantageous cognitive trait has been pushed close to a fitness “cliff edge” beyond which failure is likely, just as strong selection for speed in racehorses has made their lower leg bones long, light, and thin, but vulnerable to breaking. The neural mechanism could involve neuron pruning, cortical folding, or any number of other traits that give major benefits up to some threshold beyond which failure becomes likely.

Substance Abuse

The devastation and early death resulting from substance abuse selects against the alleles that increase vulnerability. However, pure substances and means to administer them have been reliably and readily available for far too few generations for selection to have a big effect. From this perspective, our vulnerability to substance abuse is a product of a mismatch with modern environments. Chemicals mediate the brain’s motivation and learning systems, so it should be no surprise that exogenous chemicals can hijack those systems. The amazing thing is that so many people can use drugs and alcohol without major problems. Active efforts are underway to understand why some people have brain mechanisms that make them especially vulnerable. It would be most interesting to see how people with high and low levels of vulnerability behave in environments where substances of abuse are not readily available. Do they use different strategies when foraging for food? Are their interpersonal relationships different? Answering these questions could lead to new behavioral tests that estimate vulnerability.

Eating Disorders

Anorexia and bulimia have likely become more common in the past century. The predisposing alleles are almost certainly quirks without major effects on fitness until they interact with modern environments. Developmental and personality factors strongly influence who gets an eating disorder. However, the shared human vulnerability seems to result from evolved nutrition regulation mechanisms interacting with novel environmental exposures. Good candidates include the ready availability of every imaginable kind of food, a resulting epidemic of obesity, and media that portray slimmer-than-real bodies. Most serious eating disorders are initiated by a strict diet. The resulting binge eating would be life-saving in a famine, but it causes panic and guilt in dieters and increases resolve to more strictly restrict intake, creating a vicious cycle. Wild fluctuations in calorie intake in ancestral times aroused a mechanism that deposits extra fat stores as insurance against insecure food supplies, so it is unsurprising that dieting often results in weight gain. The knowledge provides some patients with a powerful motive for sensible eating.

Child Abuse

It makes no evolutionary sense for parents to harm their own children. This led evolutionary psychologists to investigate whether the risk of death of a child depends on how it is related to the parents. In some studies, death rates from child abuse are as much as 80 times higher if there is a step-parent in the home. This research was inspired by studies of vervet monkeys that found infanticide to be routine when a new male takes over a harem. Eliminating nursing infants speeds return to estrus in the females, thus increasing the reproductive success of the new male during the period before another male displaces him. The different human mating system means that infanticide in humans gives no such advantage and was not shaped by selection. However, not being with both parents from the start seems to interfere with the bonding that usually protects children from harm.

This research must be viewed very tentatively, as not all data confirms it. In primates more closely related to humans then vervet monkeys, such as chimpanzees, infanticide is very rare. Furthermore, making connections between animal and human data is always complex. And although data on child homicide in, for example, Canada does support this hypothesis, other countries, for example, Sweden, found no difference in child homicide rates between genetic and nongenetically related children.

Extended early contact also seems to be the signal that makes parents and children uninterested in each other as sex partners. For instance, children raised together from their early years in a kibbutz usually experience embarrassment and disgust at the idea of marrying another member of the group. Over evolutionary time, this incest inhibition mechanism has increased reproductive success by reducing the risk of having children with many pairs of identical deleterious recessive genes.

In this example, cultural prohibitions amplify already existing evolved inhibitions. The relevance to psychiatry is all too obvious in cases where such inhibitions are weak because a parent has little early contact with a child. It is interesting to consider if the development of such inhibitions is related to early Oedipal wishes and their subsequent repression.

Sociopathy

The range of prosocial tendencies in humans is breathtaking. Some individuals lie awake at night wondering if some small oversight might have caused others inconvenience, while sociopaths take pleasure in deceiving others and sadistically causing them pain. In this case, selection seems not to have settled on a narrow optimal mean. Frequency-dependent selection has been proposed as a possible explanation.

If people with sociopathic tendencies do well in groups when there are many cooperators to exploit but badly in groups where many others are also sociopathic, this could maintain a small proportion of sociopaths in the population. Their tendency toward sexual license and lack of commitment to families and children could give a reproductive advantage until the proportion of sociopathic individuals becomes high enough that they must deal with each other and until cooperative individuals have developed strong abilities to detect and avoid them. This hypothesis is supported by the high heritability for sociopathy, but it is undermined by evidence for minor neurologic abnormalities in many such individuals and by the role of early abuse and neglect. From a longer-term perspective, the presumed relatively recent evolution of strong prosocial tendencies may turn out to be important. Note that these evolutionary explanations say little about why some people become sociopathic and others do not. They only explain how extreme prosocial traits may give selective advantages and why not all individuals may have such traits.

Personality Disorders

Other personality disorders are also characterized by rigid extremes of social strategies. People with obsessive-compulsive personality traits do their duty to an extreme, expect others to be equally conscientious, and are constantly disappointed. Ordinary neurotics are not so rigid, but they also invest huge proportions of life effort into trying to please others, efforts that often result in disappointment. Those with paranoid tendencies expect that others will deceive or harm them, and their lack of trust means they have difficulty finding relationship partners who can correct their misperception. Those with anxious, avoidant personalities invest vastly excessive proportions of life energy into protecting against possible harm in general. Dependent personality tendencies result in overwhelming investments in particular relationships, and in preserving those relationships. From an evolutionary point of view, personality disorders are not interpreted as adaptations, but as extremes of normal personality dimensions that reflect different social strategies.

FUTURE DIRECTIONS

Evolutionary biology provides psychiatry with a missing solid foundation for understanding behavior, relationships, and emotions. Clinicians who understand the evolutionary origins and functions of emotions have tools that allow them to better understand disorders of emotions. Those who understand the evolutionary origins of capacities for relationships are better able to deal with problematic relationships and the emotions they arouse. Those who understand how natural selection has shaped extreme prosocial tendencies in humans are better able to understand social anxiety and neurosis. Those who recognize personality characteristics as social strategies have a framework for understanding personality disorders. Most globally, clinicians who grasp the distinction between proximate and evolutionary explanations are well prepared to integrate their knowledge of factors increasing risks for individuals with their knowledge about the evolutionary reasons why all members of the species are vulnerable to a particular disorder.

The implications for research are perhaps even more important. Huge efforts to try to identify specific disorders based on specific brain abnormalities will eventually succeed for some disorders, but others will turn out to be, like epilepsy or congestive heart failure, system failures that can have many causes. Severe brain disorders such as autism and schizophrenia may turn out to have a specific, consistent neuropathology, but an evolutionary view suggests that we should be open to the possibility that they result from systems that have been pushed by selection close to some fitness cliff-edge, or that they are otherwise intrinsically vulnerable to failure for other good evolutionary reasons.

Implications for studies of treatment are substantial. Studies of drugs to relieve emotional suffering are often framed as normalizing neurotransmitter abnormalities. However, recognizing that even negative emotions are useful suggests that drugs relieving aversive emotions are like drugs that relieve cough or fever by blocking normal mediating mechanisms. Studies of cognitive-behavioral interventions increasingly go beyond simple learning theory to also consider social factors that influence schemas, and the advantages as well as the disadvantages of distorted thinking. They also increasingly recognize the power of social groups and relationships to get people to carry out behavioral exercises that are difficult, but essential. Interpersonal therapy analyzes social roles and conflicts that almost invariably involve struggles to get important reproductive resources, and trade-offs among conflicting strategies, roles, and relationships.

This chapter provides only the briefest sketch of a basic science whose vast implications for psychiatric research and treatment are just beginning to be explored. Recognizing the opportunities will lead to increased support for research that should result in major advances.

ACKNOWLEDGMENT

Thanks to Adam Hunt for useful suggestions.

Quantitative and Experimental Methods in Psychiatry

5.1 Quantitative and Experimental Methods in Psychiatry: Epidemiology

Diana E. Clarke, Ph.D., M.Sc., Lamyaa Yousif, M.D., Ph.D., M.Sc., Nusrat Rahman, Ph.D., Adrienne Grzenda, M.D., Ph.D., M.S., and William E. Narrow, M.D., M.P.H.

BACKGROUND

Epidemiology describes how often disease occurs in populations, the rates at which they change through time, and the factors that explain their occurrence. A field that studies populations as contrasted to individuals, it provides useful information for public health decisions about prevention, treatment, and the social costs of illnesses. This chapter focuses on psychiatric epidemiology, where the illnesses of interest are psychiatric disorders. Because mental disorders more closely follow a chronic pattern, analytical models used in psychiatric epidemiology resemble those used in other chronic illnesses, as opposed to classic acute or infectious disease models.

In 1957, Stuart L. Morris described the uses of epidemiology, which are still relevant today and readily applied to psychiatric epidemiology. These uses of epidemiology included historical study, community diagnosis, health services utilization, completing the clinical picture, identification of syndromes, assessing individual risks, and identifying causes. These seven uses of epidemiology are applied to psychiatric epidemiology below:

Historical study—Findings from epidemiologic studies can be compared through time. A classic example is the finding of a shift in the major causes of mortality that accompanies economic development, from infectious diseases to chronic diseases such as cancer. For psychiatric disorders, such historical comparisons are difficult due to radical changes in diagnostic customs since the 1970s and a relatively recent focus on community diagnosis, as opposed to diagnosis in treated populations such as hospital discharge diagnoses. Research with historical data examines issues such as changes in the incidence or prevalence of disorders over time due to factors such as changing population demographics. For example, as the U.S. “baby boomer” population (those born between 1946 and 1964) continues to age, rates of age-related disorders such as major neurocognitive disorder due to Alzheimer disease are projected to increase for future years compared to current rates.

Community diagnosis—Epidemiologic studies provide a picture of the health status, morbidity, and mortality characteristics of a population and its subgroups. These data permit the identification and characterization of vulnerable populations and their critical health service needs. The burden of an illness on society is estimated in terms of reduced worker productivity, treatment costs, and premature mortality. The World Health Organization Global Burden of Disease project is discussed at the end of this chapter.

Health services utilization—Epidemiologic studies provide valuable information on a population’s treatment needs and its current level of treatment demand. Demand for treatment is defined as the current level of service use in the population. Epidemiologic studies performed since the 1970s have documented the “de facto mental health service system” in the United States as characterized by traditional specialty treatment settings and service use in primary medical care, social services, school, and alternative medicine settings. The primary care setting is an especially important and highly used source of mental health care globally, highlighting the need for workers in these settings to be familiar with accurate psychiatric diagnosis and treatment strategies.

Treatment needs for persons with psychiatric disorders, as opposed to many other medical disorders, have not been well-defined for population-level purposes. For medical disorders such as a bone fracture or sepsis, the assignment of a diagnosis implies an intrinsic treatment need. Psychiatric disorders, on the other hand, are often on a continuum with mood and emotional states characterized by features including duration, frequency, intensity, and appropriateness. The diagnostic threshold distinguishing a typical reaction from a disordered reaction is often unclear and largely dependent on the degree of functional impairment to the individual. Further, psychiatric conditions not reaching full diagnostic criteria may still cause significant distress or disability to an individual. Symptoms may also spontaneously remit without treatment, particularly in mild cases. For these reasons, the need for treatment is an unresolved concept in psychiatric epidemiology. Various combinations of symptoms and symptom severity, levels of distress and disability, and duration of illness are used in current diagnostic criteria. These definitions also carry implications for defining the concepts of treatment and prevention. However, no matter how treatment needs are defined, a large, unmet need for mental health treatment is well documented in the United States and other countries.

Completing the clinical picture—Community-based epidemiologic studies provide data on the natural history of a disorder, including risk and protective factors, prodromal states, the onset of illness, and disease progression. The large number of persons with psychiatric disorders who need treatment but do not receive it has implications for the study of these disorders. Persons who seek treatment are likely to have more severe cases of disorder, a longer duration of the disorder, and more comorbid conditions. Sociodemographic and socioeconomic factors also influence which cases of the disorder are seen for treatment. Hence, samples drawn from clinical settings are different from those drawn from community settings and may thus give biased information about the nature of a disorder. A well-known example of this difference is the Berkson bias, which describes erroneous conclusions about risk factors that may be drawn about a disorder simply due to higher rates of comorbidity in hospitalized patients compared to nonhospitalized patients.

Identification of syndromes—Psychiatric disorders lacked well-defined diagnostic categories until the publication of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) in 1980. The dearth of objective validating tests for the disorders listed in DSM, across editions, means that included disorders are only approximations of underlying disease states, and the diagnostic criteria represent the best available hypotheses for detecting these underlying diseases. Examination of the diagnostic criteria in clinical and research settings since the release of DSM-III suggests that the categorical, symptom-based approach to diagnosis has significant limitations, both in its ability to describe the clinical complexity of patients and to facilitate the discovery of the underlying causes of mental illnesses. Therefore, efforts were made in the development of DSM-5 to incorporate cross-cutting dimensional symptom assessments as supplements to the categorical diagnostic criteria. The Research Domain Criteria (RDoC) project, sponsored by the National Institute of Mental Health, examines the neuroscience of basic behavioral domains with the goal of facilitating etiologic research and ultimately improving diagnosis precision and reducing time to treatment.

Epidemiologic research can support the scientific investigation of syndromes by assessing their prevalence in the community, associated disabilities, and their relationship to other disorders. Syndromes that are highly prevalent in the community, with little associated disability, are more likely to represent expected variations of human behavior than disorders. A syndrome that is highly associated with another disorder is likely to be a variant or subtype of that disorder. Much attention has been drawn to the relationship between depression, anxiety, and somatization, which are highly comorbid in the community and treatment settings.

Assessing individual risks—The results of epidemiologic studies are important in assessing the likelihood that an individual will develop a disease. A well-known example is that individuals who have high cholesterol levels, hypertension, and smoke exhibit significantly increased cardiovascular disease risk. Such findings are important for treatment and preventive interventions at the individual level, as exemplified by widespread acceptance of efforts to promote a healthy diet, smoking cessation, and treatment of hypertension. Epidemiologic findings on risk also figure into actuarial determinations for insurance coverage purposes and decisions on the marketing of pharmaceuticals to certain population groups. Risk and protective factors for psychiatric disorders are ever-evolving, but the translation to individual-level preventive interventions is still at a nascent stage, despite awareness that early treatment is the key to mitigating lasting adverse consequences.

Identifying causes—One of the ultimate goals of epidemiologic investigations is to elucidate the causes of disorders. Once the cause of a disorder is found, targeted treatments and preventive interventions can be developed to help reduce the burdens of the disorder in the community. For complex conditions, such as psychiatric disorders, causes are often multifactorial and interdependent, involving genetic and environmental factors. The mechanisms by which all of these factors interact to influence disease presentation or its progression are generally not well- elucidated. The relative impact of genetic versus environmental factors varies by disorder. One of the best-known examples of a specific gene-environment interaction in a psychiatric disorder involves a polymorphism of the promoter region of the serotonin transporter gene and stressful life events in the development of major depression as an adult. However, more research is required before these findings are actionable in the treatment and prevention of major depressive disorder.

MEASURES OF DISEASE FREQUENCY

Prevalence

A useful measure to quantify the occurrence of a specific condition in a population is the prevalence estimate, a ratio describing the number of people with a disorder in a specific population in a designated time period. The three elements important to prevalence estimation are case definition, target population, and time.

$$\text{Prevalence rate} = \frac{\text{number of cases identified in a specified period of time}}{\text{number of people in the population at the same time}}$$

Commonly used prevalence rates include:

Current (Point and 1-Month) Prevalence. *Current (Point and 1-Month) Prevalence* describes people with a disorder at a specified point in time and is referred to as the point prevalence. While the point prevalence is the best estimate of the “current” prevalence of a disorder, it is difficult to estimate for mental disorders in the general population since mental disorder diagnosis requires multiple symptoms to cluster together for specific time periods, and these symptoms may wax and wane on a daily basis. Therefore the 1-month prevalence rate has been more frequently used to describe the percentage of people who currently have a mental disorder. This time period describes people in a specified population whose symptoms have met the criteria for a disorder at any point in the past month.

1-Year Prevalence. *1-Year Prevalence* describes people who have had a disorder at any time in the past year. Because service planning is done on an annual basis, planners are most interested in how many people can be expected to have a disorder in a given year. If an assumption is made that mental disorder prevalence rates do not change greatly from year to year, and there have been no significant demographic changes in the population of interest, a 1-year prevalence rate from a recent time can be multiplied by an estimate of the total population for a given year to determine how many people in the population can be expected to have the disorder in that year.

Lifetime Prevalence. *Lifetime Prevalence* describes people who have had a disorder at any point in their lives. An accurate estimate of lifetime prevalence can be a useful tool to describe the risk of developing a disorder in a population. Lifetime prevalence is also valuable for risk factor studies. In studies of risk and protective factors, it is important to determine, as accurately as possible, who has had a disorder and who has not. The relapsing and remitting course of many mental disorders, with potentially years between episodes, makes 1-month and 1-year assessments less valuable for this purpose since true cases are likely to be counted as noncases. Lifetime prevalence is not helpful for service planning, as it will count as cases of single episodes of disorders that occurred in the remote past and have little chance of recurring in the next year. Lifetime prevalence rates are also more subject to recall bias than are prevalence estimates based on shorter time frames; that is, remotely occurring episodes of the disorder are less likely to be accurately recalled than those occurring more recently, particularly if complex diagnostic criteria are used (e.g., multiple symptoms, age of onset, duration, and disability requirements). Lifetime prevalence estimates are generally lower in older age groups, raising the question of whether older generations were more protected from developing mental disorders than younger generations. The role of recall bias cannot be discounted in this deliberation: compared to younger respondents, older respondents have lived more years in which they could have developed a mental disorder, but also, on average, have had more years elapse between their episode of illness and the present time.

Caution is needed when interpreting prevalence rate differences over time. A shift in the distribution of a demographic factor in the population can cause such observed differences. For example, when migration increases the proportion of young people in a population, disorders more frequent in the older adults will have lower prevalence rates in the overall population, even though the prevalence remains stable in the older adult population itself. For this reason, statistical adjustments are made to account for such differences in the two populations being compared.

Incidence

At times, epidemiologists require estimates of how many new events occurred in a period of time, for example, the number of new cases of posttraumatic stress disorder since a natural disaster. Incidence rates are the measure of choice in such instances. The numerator of the incidence rate is the number of new events arising in a specified time period; the denominator is the population at risk of having an event during that time period.

$$\text{Incidence rate} = \frac{\begin{array}{c}\text{number of new cases of disorder}\\ \text{in a specified period of time}\end{array}}{\begin{array}{c}\text{people at risk for the disorder in the}\\ \text{same time period (person-time)}\end{array}}$$

People who already have the disorder at the start of the time period are, by definition, taken out of the denominator for they are not at risk for developing the disorder. A new case is a person who did not have the disorder at the start of the specified time period and developed it afterward. Persons without the disorder at the start of the specified time period may or may not have had the disorder previously. When the new cases are limited to people who have never before had the disorder in question, the measure is referred to as the first incidence. Because most mental disorders are relatively rare in the population, the occurrence of new cases is also relatively rare, and the occurrence of first-incident cases is even more rare. This makes estimation of incidence rates difficult, requiring large populations-at-risk and relatively long periods of observation to accrue new cases. Most incidence rates are based on a 1-year time period. Longer periods of observation are also potentially subject to recall biases.

Measurement of the population at risk over a period of time involves several considerations. In reality, populations are often nonstationary; that is, the population at risk at the beginning of the study changes during the period of observation due to people entering the population after the study period started, dropping out of the study, moving without leaving new contact information, or dying. These individuals will have been observed for different time periods, but the data they contributed is included in the denominator as person-time at risk, an estimate of the actual time at risk that all persons contributed to a study. It is estimated as the product of the number of people at risk multiplied by the time elapsed until they were no longer at risk (became a case) or stopped being followed.

Relationship Between Prevalence and Incidence

Prevalence, incidence, and mean duration are mathematically related. The mean duration of the disorder is an indicator of the chronicity of the disorder. It is estimated as the average of the difference between the age of onset and age at the last time when criteria for the diagnosis was met. Duration is affected not only by the intrinsic characteristics of the disorder but also by external factors such as receipt of treatment. The prevalence of a disorder is proportional to incidence times duration ($P \sim I \times d$). This equation illustrates another reason why caution should be used in the interpretation of prevalence rates, as prevalence rates reflect not only increases in the number of new cases (incidence) but also the length of time that cases have the disorder (duration). When a treatment is found to cure a previously incurable condition, the prevalence of the condition can be expected to decrease. However, a treatment that extends the life of a chronic, incurable condition might actually raise its prevalence rate through the increased duration of the condition. For example, the prevalence of AIDS in the population increased after an effective treatment was found that prolonged the lives of affected patients and reduced mortality. In such cases, it is wise to employ incidence measures; relying solely on prevalence estimates makes it impossible to tell apart an increase in new cases from an improvement in survival.

Comorbidity

In psychiatry, co-occurrence of disorders, meaning individuals diagnosed with more than one mental disorder, is frequently observed in both community and clinical populations. Random co-occurrence of disorders is possible whenever the presence of one disorder does not preclude the presence of the other disorder. For common conditions, such random co-occurrences may be quite common. By definition, random co-occurrence does not imply underlying relationships between the co-occurring disorders.

The most commonly used concept of comorbidity refers to a nonrandom co-occurrence of disorders, in which the prevalence of condition A is higher in people with condition B than the prevalence of condition A in persons without condition B. This type of comorbidity has implications for the underlying processes and boundaries of the two disorders. For example, the comorbid disorders may share common risk factors or may not be separate disorders at all, but rather different presentations of the same disorder. At times, the apparent co-occurrence can be explained by artifacts of the criteria used to make the diagnoses. For example, high rates of co-occurring substance use disorders were observed in persons with DSM-III antisocial personality disorder. However, substance use was one of the symptoms that could be used to meet diagnostic criteria for both antisocial personality disorder and substance use disorder in DSM-III. Sampling bias may also create false comorbidity; for example, comorbidity is higher in treated samples than community samples, but this relationship is not related to shared etiologies.

MEASURES OF EFFECT AND ASSOCIATION

Risk, Protection, and Causation

Epidemiologic studies often aim at estimating the effects of putative risk and protective factors on the occurrence of disorders in the population. A risk factor increases the likelihood that a person possessing that factor will develop a specified outcome (such as a mental disorder) compared to a person who does not possess the factor. A protective factor decreases the likelihood that a person possessing that factor will develop the outcome compared to a person who does not possess the factor. A plausible model accounting for biologic and psychosocial risk and protective factors is a prerequisite for the interpretation of effect measures. Quantifying these effects relies on accurate identification and differentiation of cases and noncases, unambiguous definitions of the risk and protective factors in question, and accurate identification of the exposure of each case and noncase to the factor. The findings of risk or protection should not be viewed as synonymous with causation, although they may provide crucial clues in the search for causes. For example, female sex is an accepted risk factor for the development of major depressive disorder. In this case, one would not cite female sex as a cause of depression. Rather it is a measurable characteristic with a wide variety of underlying biologic and associated psychosocial factors, each of which may play a more direct causal role.

In psychiatric epidemiology, exposures can be genetic or environmental. For example, being a victim of a natural disaster is an environmental exposure and being the offspring of a depressed mother is an exposure that likely has mixed genetic and environmental aspects, even though the genetic exposure is unlikely to be precisely identified. The role of specific genetic exposures in the development of psychiatric disorders is likely to be studied with increasing frequency in the future as candidate genes for disorders are identified, and genomic science advances. Without a plausible model accounting for biologic and environmental factors, observed associations cannot be justified as contributing to causation.

The factors involved in the development of chronic diseases are numerous, complex, and intertwining, and the process by which they operate has been described as a *web of causation*. In this web of causation, causal pathways involving the main effects of interest might be modified by other, noncausal factors. These indirect modifying effects should be considered and taken into account in the initial explanatory model, to the extent possible, since the effects of unknown and unmeasured factors are always a threat to the validity of a risk factor study. The fields of epidemiology and biostatistics have developed study designs, sampling strategies, and analytic techniques to help overcome some of these difficulties in the estimation of effects, although these strategies cannot overcome the disadvantage of a poorly specified model.

Studies of causation are logistically difficult to implement and maintain and tend to be expensive. For many disorders, including psychiatric disorders, the occurrence of a new case in a population is a rare event, requiring the monitoring of large populations in order to gain a sufficient number of new cases. Also, the time span between the exposure to risk and protective factors and the onset of a disorder may be long, requiring periodic monitoring of the population to prevent drop-outs (“loss to follow-up”) and detect new exposures among the previously unexposed.

Table 5.1–1.
2 × 2 Table for Calculation of Relative Risk

		Disease		
		Present	Absent	Total
Exposure	Present	a	b	n3
	Absent	c	d	n4
	Total	n1	n2	N

Relative Risk

The classic relative effect quantification is *relative risk*, the ratio of two incidence rates. Table 5.1–1 lays out the distribution of exposed and unexposed persons who will go on to develop or not develop the disease of interest. Cell a represents persons with the exposure who go on to develop the illness, while cell b represents exposed individuals who have not developed the disease. Cell c represents unexposed persons who nonetheless have developed the disease, while cell d represents unexposed persons who have not developed the disease. The risk of developing the disease for a person with the exposure is a/a + b. The risk of developing the disease in persons who were not exposed is c/c + d. Therefore, the relative risk of developing the disease for those with compared to those without the exposure is:

$$\frac{(a/a + b)}{(c/c + d)} \text{ or } \frac{\text{incidence}_{\text{exposed}}}{\text{incidence}_{\text{unexposed}}}$$

A relative risk greater than 1 suggests that the exposure is a risk factor, and a relative risk less than 1 indicates that the exposure is a protective factor. A relative risk of 1 suggests that exposure has no effect on the onset of the disorder.

Odds Ratios as Approximations of Relative Risk

For the reasons mentioned above, studies using incident cases are not always feasible. Still, it is possible under some circumstances to design studies where prevalent cases are sampled, and risk and protective factor data are then collected (see Analytic Studies, below). In such cases, the incidence is not directly measured, and risk ratios cannot be calculated. However, with carefully chosen cases (disease present) and controls (disease absent), and accurate measurement of exposures, an approximation to the relative risk can be made by using *odds ratio.*

Table 5.1–1 can also be used to represent the different assignments that can be made in a case-control study. Cases with the exposure present are represented in cell a; cases without the exposure are in cell c. Controls with the exposure are in cell b, and controls without the exposure are in cell d. In this table, the odds of having the disease among those with the exposure is a/b. The odds of having the disease among those without the exposure is c/d. The odds ratio compares the odds of having the disease and the exposure to the odds of having the disease without the exposure.

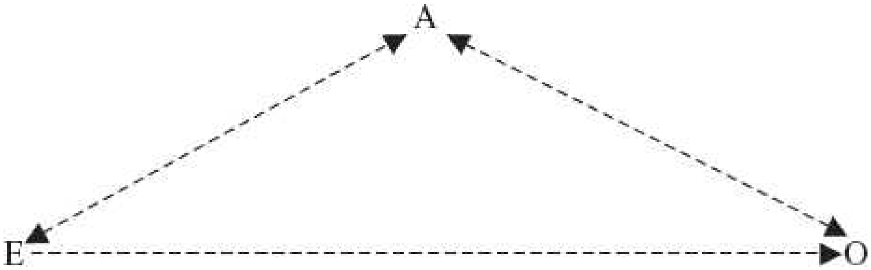
$$\text{Odds ratio} = \frac{a/b}{c/d}$$

Simple algebraic manipulation of this formula allows a convenient way to calculate the odds ratio, the crossproduct ratio. Care must be used when calculating an odds ratio using this method to make sure that the rows and columns of the table are set up as in Table 5.1–1.

$$\text{Odds ratio (cross-product ratio)} = \frac{ad}{bc}$$

As with the relative risk, odds ratios vary around 1. An odds ratio greater than 1 indicates an association between the exposure and the presence of the disease, and an odds ratio less than 1 indicates an association between the exposure and not having the disease. An odds ratio of 1 suggests that there is no association between exposure and having or not having the disease.

Confounding. *Confounding* occurs when a third factor (A), other than the exposure of interest, is independently associated with the outcome (O) as well as with the exposure of interest (E) and is not in the causal pathway.

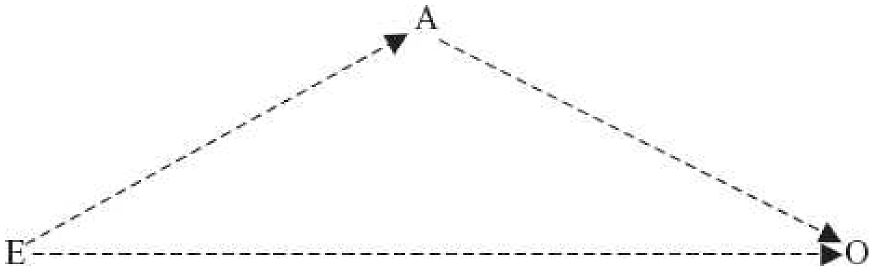


For example, studies have found that smoking is associated with suicidal behaviors. However, alcohol use is associated with smoking in individuals with and without suicidal behaviors and also is independently associated with suicidal behaviors regardless of smoking status. Therefore, alcohol use is considered a confounder of the relationship between smoking and suicidal behaviors. In order to interpret the effect of smoking on the risk of suicidal behaviors, adjustments must be made for alcohol use.

Confounding can distort the relationship between exposure and outcome in any direction, either reducing or augmenting the size of the effect. Therefore, when measuring the effect of an exposure, other factors that might explain the outcome should be measured. When potential confounders have been measured, analytic and statistical modeling techniques such as stratification and regression analysis can help disentangle the “true” contribution of the exposure from that of the confounding factors. When such techniques are used, the results of the analysis are referred to as “adjusted” or “controlled” for the confounding factors (e.g., an adjusted odds ratio for the effect of smoking on suicidal behavior controlling for alcohol use). Unmeasured confounders, by definition, cannot be accounted for by these techniques, and their potential presence should always be considered when interpreting the results of an analysis.

Mediation. Mediation occurs when a third factor (A) in the causal pathway explains the mechanism through which the exposure (E) leads to the outcome (O). The mediator variable (A) must be independently related to, and occur temporally after, the exposure variable (E).

For example, cognitive therapy can reduce depression by reducing anxiety. In this example, anxiety is a mediator of the relationship between cognitive therapy and depression; it provides a mechanism by which cognitive therapy and depression are related. Mediation can be partial, where the third factor only explains some but not all of the relationship between the exposure and outcome, or complete, where the mediator explains all of the relationship between the exposure and the outcome. In mediation analysis, the relationship between exposure and outcome is broken down into direct (i.e., E directly affects O) and indirect (i.e., E affects O only through A) components.



Effect Modification/Moderation. *Moderation* occurs when a third factor (A), at different levels (i.e., A_1 vs. A_2), impacts the relationship between the exposure and outcome differently. Furthermore, for the third factor (A) to be a moderator, it must temporally precede and be independent of the exposure. For example, the relationship between antidepressant use and depression recovery is found to be different for individuals who are adherent compared to those who are nonadherent. In this example, the level of adherence moderates the relationship between antidepressant use and depression recovery. Typically, stratified analyses (i.e., stratification based on different levels of A) or inclusion of an interaction term between the third factor (A) and the exposure is used to identify *effect modification*.

Attributable Fraction. The *attributable fraction* is used to study the effect of a risk factor on the incidence of a disease. Attributable fractions can be calculated for those exposed to a risk factor or for an entire population and are also referred to as etiologic fractions or *population-attributable risks*. The attributable fraction for those exposed to a risk factor shows how much excess disease can be attributed to the risk factor among those exposed. It is calculated by dividing the excess risk for the risk factor by the incidence rate in the exposed group.

$$\text{Attributable fraction for exposed group} = \frac{\text{incidence}_{\text{exposed}} - \text{incidence}_{\text{unexposed}}}{\text{incidence}_{\text{exposed}}}$$

The population-attributable fraction tells us how much excess disease in a population can be attributed to a risk factor. It is calculated as follows:

$$\text{Population attributable fraction} = \frac{\text{incidence}_{\text{total}} - \text{incidence}_{\text{unexposed}}}{\text{incidence}_{\text{total}}}$$

If the risk factor is related to the disease in a causal way, then attributable fractions can be used to determine the amount of disease reduction that would occur if the risk factor was prevented. The prevalence of exposure to the risk factor will affect its population-attributable fraction. A rare exposure, no matter how strongly related to the disease, will result in a small population attributable fraction.

EPIDEMIOLOGIC STUDY DESIGNS

The choice of the design for an epidemiologic study depends on several factors. First and foremost, the study's design must be appropriate to the research question that the study is addressing; not all types of studies can address all types of questions. At the most basic level, study designs can be divided into *experimental* and *observational*. In an experimental study, the researcher can control the exposure, which is usually a treatment or preventive intervention. In nonexperimental, or observational, studies, the researcher is only able to observe and quantify the effect of the exposure, which cannot be manipulated as in an experimental study. Observational studies can be further characterized as descriptive or analytic.

Experimental Studies

In standard clinical trials, the exposure is a treatment (usually medication, but psychotherapies have been increasingly subjected to clinical trial designs), with the goal being to assess the *efficacy* of the treatment, that is, whether the treatment produces the desired outcome for the condition it is supposed to treat. Desired outcomes may include cure or remission of disorders, decrease in symptom levels, prevention of disability, or increased survival time. Efficacy trials tend to use highly selected subjects possessing the disorder of interest, with as few potential confounding factors as possible. The strict inclusion and exclusion criteria for enrollment into an efficacy trial allow for a purer experimental milieu, but they do not reflect clinical reality. Over the past two decades, it has been recognized that treatment outcomes in routine clinical practice do not always mirror the results of efficacy trials and that clinical trials should also reflect the reality of routine practice. In routine practice settings, as opposed to efficacy trials, treatments may be changed or discontinued because of nonresponse, side effects, or patient preference, and patients may have comorbid mental or general medical disorders, take multiple medications, use substances, and not follow treatment instructions to the letter. This recognition has led to the fielding of clinical *effectiveness* trials in which a wider range of subjects is included in an effort to provide a clearer picture of how a treatment will work in clinical practice.

The standard clinical trial is controlled and randomized. Control groups receive either an inactive treatment (placebo) or a treatment already proven to be efficacious for the disorder. Control groups are necessary for comparison purposes and to account for effects that may occur regardless of the effects of experimental treatment. For example, there are often salutary effects of receiving care, even if the patient is receiving an inactive treatment; clinical improvement in the face of an inactive treatment is referred to as a placebo effect. Similarly, patients receiving inactive treatment may report side effects. The use of inactive comparison treatments is now less frequent than in previous years. Research experience has shown that there can be deleterious, long-lasting clinical consequences when psychiatric patients with a treatable disorder are not actively treated, particularly among those with severe symptoms. This raises obvious ethical issues around the use of placebos.

Random assignment of subjects to either the experimental or control condition helps to prevent bias in the outcome of the experiment by maximizing the chance that factors related to the outcome are evenly distributed between the groups. For example, subjects with more severe symptoms may be less likely to respond to treatment; preferential assignment of them to the experimental group may bias the study results in favor of the control treatment, and conversely, preferential assignment to the control group might produce a bias in favor of the experimental treatment. Another method used to increase comparability between groups is to *double-blind* the study so that neither the study staff nor the subjects themselves know to which group the assignments have been made.

The main difference between clinical trials and *prevention trials* is that subjects in prevention trials have not developed the disorder of interest. Subjects for a prevention trial can be selected from the community or from any other facility that is not a treatment center for the disorder of interest. Prevention trials are usually more costly than clinical trials, mainly because sample sizes required for these trials must be adequate to observe a sufficient number of outcomes, usually defined as incident cases of a disorder. Well-thought-out sampling strategies can help to maximize the number of subjects at risk for the study outcome while still maintaining the ability to generalize the results to the population studied. Additionally, because the period of risk for developing a disorder can be lengthy, especially compared to a circumscribed treatment period, prevention trials can take longer to complete, requiring more extensive tracking of study subjects than is needed for clinical trials. Although all guidelines for subject assignment in clinical trials apply to prevention trials, at times, randomization is not feasible in larger studies. For example, studies of the so-called *universal interventions* are applied to all members of the general population and are not feasibly randomized.

Observational Studies

There are two primary nonexperimental, observational studies in epidemiology, analytic and descriptive. Analytic studies, in which the effect of an exposure, uncontrolled by the investigator, is studied relative to a specific outcome, can be subdivided into cohort and case-control studies.

Analytic Studies. A *cohort study* is similar in concept to a clinical trial. In these studies, two cohorts of individuals without the outcome of interest are randomly chosen from a defined population, one cohort with an exposure and one without an exposure. These cohorts are then followed over time, and the rate at which the subjects in each cohort develop the outcome of interest is measured. By comparing the rates of the outcome in the two groups, the effect of the exposure can be estimated. Cohort studies have many advantages inherent in their design: onset of the outcome can be observed in real-time (as opposed to relying on recollection), and potentially confounding variables can be measured before the onset of the outcome. However, because incident cases are being measured, and the base population prevalence of these outcomes is often quite low, the sizes of the cohorts may need to be large, increasing the cost and complexity of the study. Cohort studies are also dependent on accurate measurement of exposure: sometimes such exposures are reliably obtained through administrative records (e.g., employees working in a particular industry or in the military; individuals living in a geographic area at the time of an exposure), at other times measurement of exposure must rely on the subjects' recollections, which may be inaccurate.

In contrast to cohort studies in which selection is based on exposure, with subsequent measurement of the outcome, in *case-control studies*, selection is based first on having the outcome, with subsequent measurement of past exposure. Cases with the outcome of interest are selected randomly from a population, and a control group without the outcome is randomly sampled from the same population that gave rise to the cases. Because the control group is used to estimate the distribution of the unexposed and exposed individuals in the population, it is important that the controls are sampled from the source population independently of their exposure status. Frequently, given the low prevalence of many disorders and the size of the original population, all cases are chosen. Selecting more controls than cases can increase the statistical power of the study. The rates of exposure in the case group and the control group are compared to give an estimate of the effect of the exposure on the development of the disorder. Case-control studies have the advantage of being easier to carry out than cohort studies.

Descriptive Studies. *Descriptive studies*, as their name implies, are aimed at describing the health status of a population. Descriptive studies typically include studies documenting the prevalence and incidence of disorders, the characteristics of the people who have or develop disorders (e.g., age, sex, race, education, income), and the use of health services in a population. They can be cross-sectional (study of a population sampled at a given point in time), repeated cross-sectional (studies of a population sampled and then re-sampled at several points in time), or longitudinal (studies of a population sampled once and then followed over time). Descriptive studies provide the basic data on which all other types of epidemiologic investigations are built, as well as serve as valuable resources for service planners and policymakers. A primarily descriptive focus of an epidemiologic study does not preclude analytic aims. The representative sampling of a large descriptive study can be a valuable asset for the collection of representative data for analytic studies. For example, collection of biologic samples for genetic analysis could be done in a large community sample, provided that the analytic goals are well-specified, the technology for collection and analysis is available, and the study subjects provide informed consent for the use of these samples.

SAMPLING AND SAMPLING STRATEGIES

Sampling refers to the process of selecting a subset (i.e., sample) of the population of interest for a research study (e.g., selecting a subset of college students from among all college students in the United States). The goal is to select a sample that is representative of the population of interest, which is determined by the specific research question. In order to select a representative sample of the population of interest, one needs to have an exhaustive list of the members in the population, called the sampling frame, from which the sample will be drawn. Ideally, the sampling frame should be the list of the entire population of interest—as may be the case for a population of college students—but this may not be the case depending on the size of the population of interest. For instance, the population may be too large to have a list of every member (e.g., the U.S. population). In such an instance, the researcher may rely on a list that approximates a representative sample of the population of interest.

There are two main methods of sampling: *probability* and *nonprobability sampling*. Probability sampling occurs when the sampling frame for the population of interest is known, and each unit/member within the population has a known chance, or probability, of being selected. When a random sample of the population of interest is selected, the chance of missing entire sections of the population is minimized, and the size and effect of sampling error are calculable. The results from a study that uses probability sampling can be generalized to the entire population if the study has an adequate response rate.

Two main types of probability sampling are simple and stratified random sampling. In simple random sampling, each unit in the population, as determined by the sampling frame, has an equal chance of being selected (e.g., randomly selecting 500 college students from the list of all college students in a particular state). However, if there is variability across subsamples of the population with respect to the variable of interest, simple random sampling cannot ensure that all subsamples will be represented within the selected study sample. For instance, if the variable of interest is expected to vary for males and females, and there are five times more female college students than males in the state, simple random sampling might not provide enough males for the study. When there is expected variability across subsamples of the population with respect to the variable of interest, stratified sampling is the preferred method of choice. In stratified random sampling, the sampling frame is divided into a number of nonoverlapping strata based on a factor that may affect the variable of interest (such as sex in the example above), and individuals are randomly selected from within each stratum (i.e., selecting a random sample of 250 males from among all male college students and a random sample of 250 females from among all female college students within the sampling frame). Stratified random sampling can ensure that representative samples of all relevant subsamples of the population are selected (in this example, it would ensure enough males were selected for the study of college students). Stratified random sampling provides greater statistical precision because there is less variability within a stratum compared to the variability when dealing with the entire population, as in simple random sampling.

Nonprobability sampling is used when the sampling frame is not available. With nonprobability sampling, information on entire sections of the population may be missing, which affects the ability to estimate the size and effect of the sampling error. Results from a study that uses nonprobability sampling cannot be generalized to the entire population of interest. In nonprobability sampling, subjects are selected on the basis of their accessibility or by the purposive personal judgment of the researcher. Examples of nonprobability sampling include *convenience*, *consecutive*, *quota*, and *snowball sampling*. Convenience sampling refers to the collection of sample units that are easiest to access until the desired sample size is reached (e.g., a volunteer sample). Like convenience sampling, consecutive sampling is not based on random sampling. However, in consecutive sampling, efforts are made to include all accessible sampling units typically within a specified time period. An example of consecutive sampling would be the recruitment of all patients who present to a mental health clinic from January 1 to June 30 of a specified year. Quota sampling involves the nonrandom selection of sample units based on some fixed quota that is related to one or more specific sample characteristics. Sampling is done until the quota is met, for example, adding new clinic admissions with a diagnosis of bipolar disorder to the study sample until a specified sample size is met. Snowball sampling is the method of choice when trying to sample hidden or hard-to-reach populations, such as undocumented immigrants or homeless individuals. Under such conditions, researchers may identify one or more individuals from their populations of interest and invite them to participate. These individuals are then asked to identify and recruit additional individuals until the desired sample size is attained. For example, undocumented immigrants may notify other undocumented persons to participate.

MEASUREMENT

Measurement instruments are developed in order to identify disorders and their associated characteristics in community and clinical populations. When considering a measure for use, either in a research or clinical setting, the target population on which the instrument was tested should match the population in which the instrument will be used. An instrument cannot be guaranteed to perform well in a population for which it was not developed or tested. This is a particularly important consideration when using an instrument in populations with different sociodemographic characteristics, cultures, or languages. Similar caution must be exercised when using an instrument that has been modified from its original construction. The deletion of items from an instrument, changing of item order, and addition of items may all have an effect on the performance of the instrument, no matter how small or useful the changes may seem.

Reliability

Reliability measures the ability of a measurement to produce the same results on repeated administrations. *Test–retest reliability* assesses the ability of a measure to arrive at the same result for the same subject on repeated administrations. The interval between the test and the retest should be long enough to ensure that the person's responses are based on their current condition rather than on the memory of their responses in the first test administration. If the interval is too long, however, there is an increased risk that the person's condition may have changed between test and retest. Another frequently used assessment of reliability is *inter-rater reliability*. This test describes a measurement instrument's ability to produce the same result when administered by two different raters.

The importance of reliability is obvious: if a measure cannot produce the same results on repeated administrations and across various raters, then it has limited value in assessing the presence or absence of a condition. Test–retest reliability is enhanced when the construct being assessed is stable across time, when it is specifically defined, and when the assessment instrument is standardized. In addition, reliability is more easily demonstrated when the individuals being assessed are clear cases of the disorder, not cases barely meeting the threshold for caseness. The reliability of an instrument, particularly a diagnostic instrument, is therefore generally lower when measured in a community population, where untreated cases around the diagnostic threshold abound, as opposed to a more selected population, such as a clinical population. Individuals chosen from clinical populations are more likely to fall well beyond the diagnostic threshold, are more accustomed to answering questions related to their clinical status, and are less likely to change answers on retest and less likely to fall below a diagnostic threshold.

Table 5.1–2 is used to illustrate the outcomes of inter-rater and test–retest reliability assessments, where the outcome is dichotomous—each individual must be classified as a case or a noncase. Cells-a and d represent individuals for whom there is an agreement between both raters (for an inter-rater reliability assessment) or ratings (for a test–retest assessment). Cells-b and c represent individuals for whom there is a disagreement between raters or ratings. The statistic most commonly used to describe the reliability of an instrument is the *Cohen kappa statistic*, which calculates agreement adjusted for chance. In Table 5.1–2, observed agreement is represented by (a + d)/N, chance agreement is represented by [(n1 × n3) + (n2 × n4)]/N^2.

$$\text{Kappa} = \frac{\text{observed agreement} - \text{chance agreement}}{1 - \text{chance agreement}}$$

The *kappa statistic* can vary between 0 and 1, with 0 representing agreement no better than chance and 1 representing perfect agreement. Interpretation of kappa scores between 0 and 1 has not been standardized, but guidelines suggested by Landis and Koch in 1977 are frequently used. These guidelines divide the kappa range into five equal categories (0 to 0.2, 0.2 to 0.4, 0.4 to 0.6, 0.6 to 0.8, 0.8 to 1.0). The range of 0.4 to 0.6 is termed “fair” or “moderate” agreement, and a kappa coefficient of at least 0.4 is generally considered to represent adequate reliability for a diagnostic instrument.

Validity

Validity is the extent to which an assessment instrument measures what it is purported to measure. There are several types of validity.

Content Validity. *Content Validity* is concerned with how well a measure covers the construct that is being measured. For a diagnostic instrument assessing a psychiatric disorder such as major depression, content validity might at a minimum assess how well the DSM criteria are covered. For example, an instrument that does not inquire about depressed mood or that inquires about spending sprees would have suspect content validity as a measure of major depressive disorder. Content validity also depends on the population that the instrument is meant to cover and the method by which data are gathered. For example, one would not ask men about menstrual symptoms when assessing somatic complaints, nor would one ask a respondent to estimate their current blood pressure as opposed to directly measuring it. Content validity cannot be empirically measured but rather must be assessed by expert consensus after careful examination of the characteristics of the construct that is being measured and comparison with other available instruments.

Criterion Validity. *Criterion Validity* examines the measurement instrument in relationship to a factor that is external to the measurement, known as the criterion. Criteria used to assess the validity of a measurement for a mental disorder are problematic in that there is usually no “gold standard” by which to assess the definitive presence or absence of disorder. Semistructured clinical interviews are often used as a criterion, in the absence of a gold standard, although they are also prone to some degree of error. Two types of criterion validity are commonly assessed, *concurrent validity* and *predictive validity*.

Table 5.1–2.
2 × 2 Table for Reliability Assessments

		Rater 1 or Test		
		Present	Absent	Total
Rater 2 or Retest	Present	a	b	n3
	Absent	c	d	n4
	Total	n1	n2	N

Concurrent validity is assessed when the measure being tested is administered along with another measure known to be related to the construct of interest. An example of concurrent validity was demonstrated in the *Methods for the Epidemiology of Child and Adolescent Mental Disorders* (MECA study), described below. In the MECA study, a highly structured lay interviewer-administered diagnostic instrument, the DISC-2.3, was compared to the results of a clinical interview administered at the same session. Predictive validity is assessed when the measure of interest is compared to a criterion that is measured in the future. In other words, the measure is assessed in terms of how well it predicts an outcome. Predictive validity is particularly important in assessing a test that predicts the later development of a disorder or a person’s response to treatment. Criterion validity is often expressed in terms of the sensitivity, specificity, and predictive value of a test illustrated by Table 5.1–3.

True positives, in which the test correctly identifies a case, are represented in cell a. *True negatives* in which the test correctly identifies a noncase are represented in cell d. A perfect test would categorize all persons in one of these cells. In practice, however, no test is totally accurate; these measurement errors should be minimized. Errors of measurement *include false positives*, in which the test assigns caseness to a noncase (cell b), and *false negatives*, in which the test does not recognize a case (cell c). The degree to which a test correctly assigns cases and noncases is described by the concepts of *sensitivity* and *specificity*.

Table 5.1–3.
2 × 2 Table to Determine Measures of Criterion Validity

		Criterion		
		Positive	Negative	Total
Test	Positive	a	b	n3
	Negative	c	d	n4
	Total	n1	n2	N

Sensitivity is described as the proportion of cases that are correctly assigned as cases by the test.

Sensitivity = a/n1

Specificity can be described as the proportion of noncases that are correctly assigned as noncases by the test.

Specificity = d/n2

Sensitivity and specificity vary between 0 and 1. Maximizing the sensitivity and specificity of an instrument has important ramifications. A high sensitivity assures that a minimal number of persons with a disorder will be missed by the test, an obvious necessity in clinical or screening situations. High specificity minimizes the chance that an individual will receive unnecessary treatment or confirmatory tests.

Predictive value is another measure that can be derived from data in Table 5.1–3. *Positive predictive value* is the proportion of persons who test positive for the disorder who actually have the disorder. *Negative predictive value* is the proportion of persons who test negative for the disorder who do not have the disorder.

Positive predictive value = a/n3

Negative predictive value = d/n4

Construct Validity. *Construct validity* is the most complex type of validity assessment, indicating how well the measure of interest relates to a theoretical set of concepts that, taken together, describe the condition being measured. Implicit in a determination of construct validity is a theoretical model of the condition being measured, with an explanation of how the components of the model are related. The most well-known theoretical model of the qualities of a psychiatric disorder was described in 1972 by Robins and Guze. This model posits the following components of a valid psychiatric diagnosis:

Clinical description—A clear description of the clinical syndrome is needed, which may include not only symptoms but also associated factors such as the age of onset, precipitating factors, and sex ratios.

Laboratory studies—Consistent and reliable findings on tests do much to increase the validity of a diagnosis. Such tests may include psychological tests as well as biochemical, imaging, anatomical, and physiologic tests.

Delimitation from other disorders—Robins and Guze argued that different disorders could have similar clinical descriptions and test results, so exclusion criteria should be specified to differentiate disorders, as well as to exclude borderline and doubtful cases.

Follow-up study—Once diagnosed, the natural history of a disorder (course and outcomes) should be consistent, and certainly, the diagnosis should not change over time.

Family study—An increased prevalence of the same disorder among family members lends credibility to the validity of the diagnosis.

It is clear from this list of validators that establishing construct validity is a process that involves more than a single study, unlike other tests of validity. Ideally, multiple studies should be used to replicate a validator using different measurement tools. The slow progress in establishing construct validity for psychiatric disorders indicates that further research is needed; as noted above, this may include a rethinking of the categorical model of mental disorders to include dimensional symptom assessments, as well as continued work on the neurobiology of basic mental and behavioral processes.

CASE IDENTIFICATION

Background

As in all fields of epidemiology, case identification is a key issue in psychiatric epidemiology. In contrast to illnesses where pathologic processes or lesions can be identified through imaging, cellular pathology, blood tests, and so on, making a psychiatric diagnosis relies on the self-reported history of the individual being assessed, reports of other informants, and ancillary sources of information such as past medical records. It should be noted that this state of affairs is not limited to psychiatric disorders; some neurologic disorders such as migraine headaches and multiple sclerosis, for example, lack definitive diagnostic tests, and diagnosis relies heavily on the accumulation of supportive clinically reported data.

The Diagnostic and Statistical Manual of Mental Disorders

The development of the diagnostic system for mental disorders has obvious implications for the development of psychiatric epidemiology. Although various diagnostic classifications have been in use since ancient times, the development of psychiatric epidemiology has been inextricably linked to the development of the DSM. The first edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) was published in 1952 by the American Psychiatric Association. Both DSM-I and its successor, DSM-II, published in 1968, contained glossaries that described the diagnostic categories in the manuals. Clinicians were expected to make diagnoses based on these descriptions and their clinical judgment. Given the latitude for variations in interpretation of glossary entries, along with differences in clinical training and judgment, diagnostic reliability was problematic for DSM-I and DSM-II, and clinical uptake of the diagnostic nomenclature was inconsistent. The problems with the reliability of psychiatric diagnoses were dramatically illustrated in a landmark cross-national study of diagnostic patterns, now known as the “U.S.–U.K. Study.” This study aimed to elucidate the disparities in the rates of schizophrenia and affective disorders in the United States and the United Kingdom by examining diagnostic methods. At the time, schizophrenia was diagnosed more frequently in the United States, and affective disorders were diagnosed more frequently in the United Kingdom. The study trained a group of psychiatrists from the two countries in the administration of the present state examination (PSE), a semistructured diagnostic instrument. When these psychiatrists made diagnoses with the PSE, rather than relying totally on their clinical judgments, their diagnostic patterns were similar; no country-specific differences in assignment of affective disorder or schizophrenia were found.

The transition from DSM-II to DSM-III in 1980 allowed for a more precise case definition in psychiatry and spurred a new generation of studies in psychiatric epidemiology. The DSM-III aimed to provide clinicians with a common language to describe psychiatric disorders so that a diagnosis had the same meaning regardless of the diagnostician. It also aimed to be theoretical and dispensed with many concepts in previous editions that were tied to then-prevalent and untestable psychoanalytic theories. These aims were accomplished by replacing the glossary of DSM-II with specific diagnostic criteria in DSM-III, based on symptoms that were observable or could be elicited directly from the patient. The DSM-III was accepted relatively readily and quickly became the diagnostic standard for mental health clinicians and researchers, as well as others relying on these diagnoses, such as federal, state, and local governments, regulatory agencies, the legal system, and the insurance industry.

A revision of the DSM-III-R was released in 1987 to correct inconsistencies and clarify criteria that were shown to be problematic in DSM-III. DSM-IV was released in 1994, DSM-5 in 2013, and DSM-5-TR in early 2022. DSM-5-TR included text revisions to updated sections on associated features, prevalence, development and course, risk and prognostic factors, culture, diagnostic markers, suicide, and differential diagnosis. DSM-5-TR also included a new diagnosis, prolonged grief disorder, as well as clarifications and corrections to approximately 70 criteria sets and incorporating new findings from research that has accumulated since the release of the prior edition. As discussed below, changes in the DSM diagnostic criteria have had implications for the epidemiologic measurement of mental disorders and for comparisons between studies performed with different diagnostic criteria.

The International Classification of Diseases

The *International Classification of Diseases* (ICD) is a diagnostic nomenclature maintained by the World Health Organization (WHO). It is in use in the United States and around the world as the common language for reporting basic morbidity and mortality statistics. Because psychiatric disorders are reported as morbidity statistics, the ICD and the DSM have been associated to varying degrees for many years. The DSM-I was a variant of the sixth edition of the ICD (ICD-6), and DSM-II was developed to be released in tandem with ICD-8. ICD-9 was published in 1975, only 1 year after work began on DSM-III, and implemented in 1978. The ICD-9 terminology was, therefore, more reflective of DSM-II, and its diagnostic categories did not match those in the new DSM-III. Because of dissatisfaction across all medicine with the lack of specificity in ICD-9, it was modified for use in the United States, resulting in ICD-9-CM (*Clinical Modification*). The development of the DSM-IV and the ICD-10 was more closely coordinated than any previous efforts, and the resulting systems were highly congruent, although not identical. The WHO also, for the first time, developed “Diagnostic Criteria for Research” to accompany the ICD-10 mental disorder diagnoses. As with the disorder list and nomenclature, these diagnostic criteria were usually, but not always, congruent with DSM-IV diagnostic criteria. Several diagnostic instruments have incorporated ICD-10 criteria along with DSM criteria, allowing examination of their differences and refinement of both sets of criteria. ICD-10 was published in 1992, but in contrast to most other countries, it was not quickly adopted as the official code set for the United States. The clinical modification of the ICD-10 (ICD-10-CM) was implemented in the United States on October 1, 2015. The development of DSM-5 was intended to be closely coordinated with the development of the ICD-11. However, because the release date for ICD-11 was pushed back several years, the opportunities for coordination with DSM-5 were limited. ICD-11 was adopted at the World Health Assembly in 2019, nearly 6 years after the publication of DSM-5. Due to diligent efforts by the harmonization team, the organizational structure and classification of mental disorders in the ICD-11 and the DSM-5 are more successfully aligned in comparison to the ICD-10 and DSM-IV classifications. For example, based on the published research, 30% of the disorders were identical in both DSM-5 and ICD-11, and about 10% had only minor differences.

Disability. Over the past 30 years, the consequences of mental disorders have assumed an increasingly important role in the theoretical underpinnings of epidemiologic studies and the interpretation of their data.

The concepts of clinically significant distress or impairment in functioning have been included in the DSM definition of “mental disorder” since the publication of DSM-III. To further emphasize the importance of these concepts in establishing a threshold for diagnosis, the DSM-IV added (for most disorders) a criterion requiring clinically significant distress or impairment in an important domain of functioning before a disorder could be diagnosed. This decision was criticized on conceptual grounds for its blending of two separate constructs, symptomatology and the consequences of symptomatology, as opposed to a conceptualization of a mental disorder as a combination of symptom aggregation, severity, and duration without regard to any resulting disability. The decision was reexamined during the development of DSM-5, and the revised definition of “mental disorder” in the manual states that mental disorders are “usually associated with significant distress or disability in social, occupational, or other important activities.” This change allowed the developers of DSM-5 to remove the “clinical significance criterion” of DSM-IV, which was implemented for some disorders. Although the multiaxial assessment was removed from DSM-5, the manual continued to emphasize the importance of the clinician’s assessment of the patient’s social and occupational functioning and disability for treatment planning and prediction of outcome.

The WHO has taken a leadership role in developing the theory, definitions, and classification of concepts related to health and functioning. The *International Classification of Impairments, Disabilities, and Handicaps: A Manual of Classification Relating to the Consequences of Disease* (ICIDH) was released by the WHO in 1980 and subsequently revised as the *International Classification of Impairments, Activities, and Participation: A Manual of Dimensions of Disablement and Functioning* (ICIDH-2). The next and most current version of this classification was released in 2001 and titled the *International Classification of Functioning, Disability, and Health* (ICF). This document is part of the WHO’s “family of international classifications” that includes the ICD-10 and allows coding of complementary information on health conditions and their consequences to provide a more detailed picture of the health status of an individual or a population. The ICIDH was mainly a classification of “consequences of disease” classification, while the ICF made a determined shift to classify “components of health.” Part I of the ICF covers “Functioning and Disability,” while part II covers “Contextual Factors.” Table 5.1–4 summarizes the further organization of the ICF. The ICF uses an alphanumeric coding system for three of its components: "Body Functions and Structures," "Activities and Participation," and "Environmental Factors." Personal factors (e.g., race, gender, habits, coping styles, etc.) are not associated with codes. The categories of the ICF are nested so that broad categories have a number of subcategories. For example, Chapter 1 of the "Body Functions" section describes mental functions, which are subcategorized as global mental functions and specific mental functions. Global mental functions contain eight subcategories such as temperament and personality, sleep, orientation, and consciousness. There are 14 subcategories of "Specific Mental Functions," including attention, memory, emotional, perceptual, and mental functions of language. Although the ICF is comprehensive in its description of health domains and provides a common language for describing these domains, its main users continue to be in the physical medicine and rehabilitation fields, where interventions focus more on improving functioning and removing barriers, rather than diagnosing and treating illnesses. There is no doubt, however, that the use of a standard classification of disabilities would be helpful for psychiatric research and clinical practice by drawing attention to the conceptual distinctions between disorders and their consequences.

Table 5.1–4.
Overview of the ICF

	Part 1: Functioning and Disability		Part 2: Contextual Factors	
Components	Body functions and structures	Activities and participation	Environmental factors	Personal factors
Domains	Body functions Body structures	Life areas (tasks, actions)	External influences on functioning and disability	Internal influences on functioning and disability
Constructs	Changes in body functions (physiologic) Changes in body structures (anatomical)	Capacity to execute tasks in a standard environment and Performance executing tasks in the current environment	Facilitating or hindering impact of features of the physical, social, and attitudinal world	Impact of attributes of the person
Positive Aspect	Functional and structural integrity	Activities and Participation	Facilitators	Not applicable
	Functioning			
Negative Aspect	Impairment	Activity limitation and participation restriction	Barriers, hindrances	Not applicable
	Disability			

ASSESSMENT INSTRUMENTS USED IN EPIDEMIOLOGIC STUDIES OF MENTAL DISORDERS

Diagnostic Instruments for Adult Populations

The Diagnostic Interview Schedule. The *Diagnostic Interview Schedule* (DIS) was developed in 1978 in response to two major impending events: the release of DSM-III, with its criterion-based diagnostic system, and the development of the *National Institute of Mental Health (NIMH) Epidemiologic Catchment Area* (ECA) program, which was being planned to capitalize on DSM-III's innovative new diagnostic system. Lee Robins, Ph.D., the lead developer of the DIS, wrote that there was no existing diagnostic instrument that could be used for the ECA program, not only because the DSM-III criteria sets were totally novel, but also because of limitations with the existing instruments in meeting the needs for a large community survey. Particularly important was the need for the instrument to be administered by interviewers who did not have clinical training, a necessity given the large numbers of respondents estimated for the ECA program. Other requirements for the diagnostic instrument included the ability to cover a broad range of major DSM diagnoses in a single administration, to assess specific DSM-III criteria from respondent reports only, without the use of medical records or outside informants, and also to be acceptable and comprehensible to a general adult population. The *Renard Diagnostic Interview* (RDI), developed at Washington University in St. Louis and based on Feighner diagnostic criteria, was felt to represent a suitable model for the ECA program's diagnostic instrument. The RDI was developed in a clinical setting from observations of psychiatrists' clinical interviews based on Feighner criteria. The instrument was "fully structured," meaning that its questions, response options, and administration patterns were all specified and therefore did not require clinical judgment for administration or data recording. Its reliability and concurrent validity were good in clinical populations, with lay and clinical interviewers. The task of developing a diagnostic instrument for DSM-III was assigned to the RDI's authors. The DIS covered approximately 28 DSM-III diagnoses, as well as diagnoses based on the earlier Feighner criteria and Research Diagnostic Criteria (RDC). The DIS generally assessed symptomatology first on a lifetime basis (i.e., "Have you ever had [symptom…]"?) and then assessed clustering of the positive lifetime symptoms into an episode. If symptoms did cluster together at the same time, an assessment of recency was made, so that period prevalence estimates could be made (e.g., 1-year, 6-month, 1-month prevalence rates). Like the RDI, the DIS attempted to distinguish "true" psychiatric symptoms or syndromes from normal reactions to life events and from conditions stemming directly from general medical conditions or the use of substances. Questions assessing the former situation were referred to as *clinical significance* questions; questions assessing the latter situation were referred to as the *probe flow* questions, named after the “probe flow chart” from which interviewers read these questions. The highly structured nature of the DIS allowed diagnoses to be made by computer via a diagnostic algorithm. This diagnostic algorithm allowed a diagnosis to be made free from any diagnostic custom or clinical interpretation of the interviewer, and along with the operationalized DSM-III criteria and the highly structured interview format, allowed a reliable diagnosis to be made. Testing showed that the DIS achieved the DSM-III’s goal of diagnostic reliability and that concurrent validity with a clinical research interview was reasonably strong. The DIS was updated to account for changes from DSM-IIIR to DSM-IV and to take advantage of new survey techniques and lessons learned from surveys using the DIS and similar diagnostic instruments. For instance, assessment of disability in the context of mental disorders was greatly expanded, diagnostic coverage was expanded to include disorders of childhood and an updated assessment of cognitive impairment, and there is less frequent use of skip-outs (where respondents who deny a cardinal symptom of a disorder are not asked any other symptoms of the disorder). The DIS has been superseded by the Composite International Diagnostic Interview (CIDI).

The Composite International Diagnostic Interview. The *Composite International Diagnostic Interview* (CIDI) was first developed in the early 1980s at the request of the U.S. Alcohol, Drug Abuse, and Mental Health Administration and the WHO, which had formed a Joint Project on Diagnosis and Classification. Originally designed to incorporate questions from both the DIS (DSM-III) and the *Present State Examination* for expanded use in epidemiologic studies worldwide, it was subsequently modified to cover other diagnostic classifications, including DSM-III-R, DSM-IV, and ICD-10. The CIDI was based largely on the DIS and shared many of its questions and characteristics, including highly structured administration and scoring, assessment of psychopathology beginning at a lifetime level, and use of clinical significance and probe questions. Taking advantage of the increasingly rapid uptake of computers throughout the world, a computerized version of the CIDI was developed.

An expanded module for detailed examination of substance use disorders was also developed, called the CIDI-SAM. One of the intended first uses of the CIDI was the *National Comorbidity Survey* (NCS).

The Composite International Diagnostic Interview, University of Michigan Version. The paper-and-pencil administered DSM-III-R/ICD-10 version of the CIDI was modified by the investigators in the NCS, which was conducted out of the University of Michigan. The resulting instrument was called the UM-CIDI. The UM-CIDI was thought to bring major improvements to the CIDI while still maintaining the basic CIDI structure. Nonetheless, the developers of the modified instrument acknowledged that the decision to modify the instrument was not agreed on by all of the original CIDI developers. Among the modifications made in the UM-CIDI were changes in the layout of the instrument form; the addition of an introductory question asking the respondent if they are willing to think carefully in order to provide the interviewer with accurate information; deletion of diagnoses with low reliability or of secondary importance to the goals of the NCS; using the CIDI psychosis module as a screener for follow-up clinical interviews, rather than as a self-contained diagnostic module; moving the diagnostic stem questions to their own section at the beginning of the interview; reordering questions; adding and rewriting questions for clarity; adding notes to help interviewers and reduce the amount of memorization required of them; changing the methods of administering the probe flow questions, and adding a respondent booklet with visual cues. Although many of these modifications in the UM-CIDI did address problems detected in previous usages of the DIS and the CIDI, it was not clear whether they all represented improvements when implemented in a major household survey such as the NCS. The differences between the UM-CIDI and the DIS were, therefore, among the primary reasons cited for the disparities in prevalence rates between the ECA and the NCS. Attempts to reconcile these prevalence rates stimulated a critical examination of the instruments and survey methods in these two landmark surveys, as discussed below.

The Composite International Diagnostic Interview, World Mental Health Surveys Version. The CIDI underwent further modification in anticipation of the WHO WMH Survey Initiative. It had been recognized that although the CIDI provided a common diagnostic assessment, it did not provide guidance on other domains critical to large-scale epidemiologic surveys. Thus, it was difficult to compare risk factors for disorders, consequences of disorders, patterns of disorders, and correlates of service use across surveys. The WMH CIDI was created to address these inconsistencies in assessments. It consists of seven sections: Screening and lifetime review, disorders, functioning, and physical disorders, treatment, risk factors, socio-demographics, and a methodologic section. The interview is designed to be conducted in two parts so that interviews can be ended for a subset of subjects who do not meet the criteria for lifetime psychopathology. A number of changes were made to the CIDI's diagnostic questions to improve the quality of responses, and several new diagnoses were added, such as intermittent explosive disorder, separation anxiety disorder, and attention deficit/hyperactivity disorder. A fuller assessment of disability was instituted, including expanded diagnostic-level clinical significance questions, a modified *WHO Disability Assessment Schedule* (WHODAS), and detailed questions on work performance. New sections on pharmacoepidemiology, nonspecific psychological distress, family burden, and childhood experiences were also included. Research on the validity of this instrument across the diverse range of nations in the WMH Survey Initiative is ongoing. The CIDI 5.0 and WMH CIDI 5.0 were updated with diagnostic criteria after the ICD-10 and the DSM-5.

The Alcohol Use Disorder and Associated Disabilities Interview Schedule. The *Alcohol Use Disorder and Associated Disabilities Interview Schedule* (AUDADIS) was originally developed at the National Institute on Alcoholism and Alcohol Abuse (NIAAA) in 1989, with a focus on substance use disorders and the mental disorders commonly comorbid with them. It was subsequently updated for DSM-IV and DSM-5 diagnostic criteria. The AUDADIS-5, based on DSM-5 diagnostic criteria, was completed before the release of the DSM-5, although the developers of the instrument note that the criteria for the disorders covered in the instrument were substantially finalized by 2011. It provides an assessment of criteria for substance use disorders including alcohol, tobacco, and other drugs; depressive and bipolar disorders; posttraumatic stress disorder; and personality disorders. The AUDADIS has been used to make DSM diagnoses in the NIAAA National Longitudinal Alcohol Epidemiologic Survey (NLAES) and the three versions of the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC). As with other instruments used in large epidemiologic surveys, it is fully structured, computerized, and can be administered by lay interviewers.

Structured Clinical Interview for DSM-IV (SCID). The *Structured Clinical Interview for DSM-IV* (SCID) is a semistructured interview guide for making diagnoses according to the criteria published in the DSM. The SCID was developed and piloted in the years following the publication of the DSM-III. Initially, it had 2 modules: SCID-P (patient), which was designed for use with patients with mental health issues. The other version, SCID-NP (Nonpatient), was designed for use in surveys. SCID-IV was published in 1994; it was based on DSM-IV criteria and had two versions, SCID-I and SCID-II. SCID-I assessed mental and substance use disorders while SCID-II assessed personality disorders. Following the release of DSM-5, the SCID for DSM-5 (SCID-5) was published in 2013. SCID-5 has many sub-types, including the Research Version (SCID-5-RV), Clinician Version (SCID-5-CV), Clinical Trials Version (SCID-5-CT), Personality Disorders Version (SCID-5-PD) as well as an Alternative Model for Personality Disorders Version (SCID-5-AMPD). SCID-5 is intended for interviewing adult individuals. A child and adolescent version of the SCID is currently being developed. The SCID is administered by either a clinician or trained mental health professional who is familiar with the DSM-5 classification and diagnostic criteria. It can be used to interview mental health patients or individuals with no mental health diagnosis as part of a survey questionnaire.

Diagnostic Interviews for Child and Adolescent Epidemiology

The development of diagnostic interviews for child and adolescent psychiatric epidemiology has paralleled that of instrument development for adult populations. However, the complexities involved in obtaining diagnoses in these populations and funding priorities placed on adult research have resulted in somewhat slower progress.

In 1969 a semistructured instrument patterned after the Renard Diagnostic Interview was developed, the *Diagnostic Interview for Children and Adolescents* (DICA). The development of the DIS for adults in the late 1970s spurred much interest in developing a fully structured lay interview schedule for assessing DSM-III diagnoses in children and adolescents. There is currently no available DSM-5 version of the DICA.

Under the sponsorship of the NIMH, the first version of the *Diagnostic Interview Schedule for Children* (DISC), covering DSM-III diagnoses, was developed in the early 1980s, and work on the DISC-R, covering DSM-III-R diagnoses, was started in 1985. Refinements of the DISC-R led to the DISC-2.1 and -2.3, the latter version being extensively tested for reliability and validity in the *Methods for the Epidemiology of Child and Adolescent Mental Disorders* (MECA) study. Findings from the MECA study led to the DISC-IV, which covers DSM-IV (and also DSM-III-R and ICD-10) disorders. The DISC-IV assesses over 30 disorders, organized into 19 diagnostic sections. The DISC-IV is a fully structured diagnostic interview that is suitable for administration by lay interviewers. A computer-assisted version (C-DISC) has been developed to simplify interviewer administration and reduce errors and costs. The DISC-IV has matching parent and child/youth versions (DISC-P and DISC-C); a partial teacher version (DISC-T) is also available. The DISC-P can be administered to parents of children ages 6 to 17 years; the DISC-C can be administered to children ages 9 to 17 years; the DISC-T is suitable for teachers of elementary school-age children. Symptoms are assessed on a past-year and past-month basis. An optional "whole-life" module was developed for administration at the end of the interview. Questions on age and context of onset, receipt of treatment, and distress and disability are asked at the end of each diagnostic section if a respondent meets a predetermined number of symptoms for that diagnosis. Diagnoses are made by computer algorithms. Diagnostic Interview Schedule for Children, Version 5 (DISC-5) includes updates to both the ADHD and tic disorder modules to reflect changes in DSM-5 criteria. Although the DISC is the most widely used epidemiologic diagnostic instrument in child and adolescent populations, other instruments are in use.

The *Child and Adolescent Psychiatric Assessment* (CAPA), developed at Duke University, was used in the Great Smoky Mountains Study. The CAPA provides DSM-IV and ICD-10 diagnoses with a high level of detail and can be administered by lay interviewers. It requires intensive training to provide the interviewers with a sufficient level of judgment to make decisions on the presence or absence of symptoms (referred to as an "interviewer-based" approach). However, with training and ongoing monitoring of interviewers, the CAPA works well in community surveys with children and adolescents ages 9 to 17 and their parents. The developers of the CAPA have also developed the Young Adult Psychiatric

Assessment (YAPA) for respondents aged 18 and over and the Preschool Age Psychiatric Assessment (PAPA) for administration to parents of 2- to 5-year-old children. The DICA was updated to provide DSM-IV diagnoses; it is a semistructured instrument that allows interviewers to probe responses. A DSM-5 version of the CAPA is available and includes questions related to depression, anxiety, oppositional defiant disorder, conduct disorder, ADHD, and impairment modules.

Kiddie-Schedule for Affective Disorders and Schizophrenia (K-SADS) was adapted from the SADS (Schedule for Affective Disorders and Schizophrenia) questionnaire to be used in children ages 6 to 18 years old. The K-SADS is a semistructured interview that measures past and current symptoms of mood, anxiety, psychotic, and disruptive behavior disorder. There are multiple versions of K-SADS developed by different groups. The lifetime version of K-SADS (K-SADS-PL DSM-5) was developed in 2016 to make it more compatible with DSM-5. Prior to administering the interview portion of K-SADS-PL, participants complete the DSM-5 cross-cutting 25-item symptom rating scales, responses of which are then taken into account in assessing the interview responses.

Instruments to Assess Disability and Impairment

There are very few instruments that have been developed to assess disability in community-based epidemiologic surveys. Most instruments require clinical training to administer and have been developed for patient populations. The development of instruments for child and adolescent populations has seen more activity than the development of instruments for adults, in part because the diagnostic threshold issues for younger populations were recognized as a particular problem.

WHO Disability Assessment Schedule. The *WHO Disability Assessment Schedule* (WHODAS 2.0) was developed to be compatible with the disability model put forth in the ICF, particularly in the activity and participation dimensions. It is fully structured and can either be administered to adult subjects by lay interviewers or be self-administered. The core instrument is self-report, but a version has been developed that can be administered to a proxy respondent. The reporting period is the past 30 days. The full version of the WHODAS 2.0 is 36 items long and assesses six domains: cognition (understanding and communicating), mobility (moving and getting around), self-care (hygiene, dressing, eating, and staying alone), getting along (interacting with other people), life activities (domestic responsibilities, leisure, work, and school), and participation (joining in community activities). There is a short version that is 12 items long. An earlier version of the WHODAS 2.0, the WHODAS II, was substantially modified for use in the WHO World Mental Health Survey Initiative. These modifications appear to have reduced the sensitivity of the instrument to detect milder levels of disability, complicating the interpretation of the results. The full version of the WHODAS 2.0 was tested in the DSM-5 field trials and was found to have good to excellent reliability for the domains and total scores in randomly sampled adults at seven clinical sites.

Disability Assessment in Child and Adolescent Populations. The *Children's Global Assessment Scale* (CGAS) is based on the adult Global Assessment Scale (GAS). Although developed for clinical use, an adaptation of this scale with nonclinical language, for use by lay interviewers, was developed for use in community surveys and was administered in the MECA survey (see below). Like the GAS, the rater assigns a single number that best describes the child's functioning, from 1 (most impaired functioning) to 100 (healthiest). A score of 70 or less indicates at least mild functional impairment. The Brief Impairment Scale (BIS) grew out of work on the Columbia Impairment Scale (CIS), which was used in the MECA survey. It is a fully structured, 23-item scale that assesses the child's functioning without tying it to any specific health conditions that the child may have. The BIS was designed to allow administration by a lay interviewer in community surveys, but it is also suitable for use in clinical settings. It is administered to an adult informant. Three domains are assessed: interpersonal relations, functioning at school or work, and self-fulfillment. Initial testing of the scale has shown that it has acceptable test–retest reliability, internal consistency, and convergent and concurrent reliability. The three domains show low intercorrelations, suggesting that they are related but separate components of the overall global functioning measured by the scale. Several other assessment scales are available but have limitations, including unidimensionality and mixing of symptom and disability constructs, or have practical difficulties for use in community surveys, such as length of administration or a need for clinical judgment in scoring.

MAJOR EPIDEMIOLOGIC SURVEYS

Large surveys do not have the timeframe or opportunity for clinical judgment. Therefore, the considerations for generating prevalence estimates typically include what instruments are used, who administers them, and how generalizable the findings are. Table 5.1–5 provides some examples of such survey instruments.

Table 5.1–5.
Examples of Survey Instruments Assessing Mental Illness

Survey Name	Instrument	Who Administers It	How Long It Takes
Epidemiologic Catchment Area (ECA) Survey of Mental Disorders	Structured interview–Family Life Survey	Trained field workers	1.5 hours
	Structured Interview–Home Interview Survey	Psychologists, social workers	2 hours
	Structured Interview–Schizophrenia and Affective Disorders Schedule-Life time version	Nonpsychiatrist mental health professionals	1.5 hours
NCS	Structured Clinical Interview for DSM-III-R (SCID)/ Clinical reappraisal interviews–based on the SCID	Trained clinical interviewers	NR
	Adult ADHD Self-Report Scale (ASRS)	Trained clinical interviewers	NR
	Health and Work Productivity Questionnaire (HPQ)	Trained clinical interviewers	NR
	K6-K10 Scales	Trained clinical interviewers	NR
	Tier 2 Disaster Survey Pilot Interview Schedule	Trained clinical interviewers	NR
NCS-A	Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS).	Trained lay interviewers	NR
NCS-R; NCS-A	World Mental Health Survey	Trained lay interviewers	2 hours

	Initiative version of the Composite International Diagnostic Interview (WMH-CIDI)/ CIDI Primary Care Screening Tool (PCST) and PCST Scoring rules/CIDI 3.0 Bipolar Screening Scales		
NSDUH	Structured Clinical Interview for DSM-5—Research Version (SCID-5 for DSM-5, Research Version; SCID-5-RV)	Clinical interviewers	30–60 minutes
	World Health Organization Disability Assessment Schedule (WHODAS)	Either self-administered or administered by an interviewer (no training required)	15–20 minutes
	Kessler-6 Psychological Distress Scale (K6)	Either self-administered or administered by an interviewer (no training required)	2 minutes
	Nicotine Dependence Syndrome Scale (NDSS) and the Fagerstrom Test of Nicotine Dependence (FTND)	Either self-administered or administered by an interviewer (no training required)	NR
NESARC-III	NIAAA Alcohol Use	Trained	NR

	Disorder and Associated Disabilities Interview Schedule (AUDADIS-5)	interviewers	
YRBSS	YRBS	Self-administered	NR

NR, not reported.

Surveys of Adult Populations

The Epidemiologic Catchment Area Program. Spurred by the release of the President’s Commission on Mental Health, chaired by First Lady Rosalynn Carter, the *Epidemiologic Catchment Area Program* (ECA) program was developed by the NIMH in conjunction with the simultaneous development of the DSM-III and the DIS. The main aims of the ECA were to estimate the prevalence of DSM-III mental disorders in community and institutional populations and determine the extent of the use of treatment services for these disorders. The ECA was carried out in five catchment areas across the United States: New Haven, Connecticut; Baltimore, Maryland; Durham, North Carolina; St. Louis, Missouri; and Los Angeles, California. In order to analyze specific subgroups of interest, oversampling of the older adults, African Americans, and Hispanics was done at selected sites. There were two samples in each site, a household sample, and an institutional sample, which included jails and nursing homes; respondents were all aged 18 or older. The final sample size was 18,571 household respondents and 2,290 institutional respondents. The ECA was designed as a longitudinal survey with three waves conducted 6 months apart with the same respondents. The first and third waves collected diagnostic and service use data, while the second wave collected service use data to reduce recall bias in service use reports. The ECA program’s sampling strategy was not nationally representative, but the investigators combined the data from the five sites and adjusted them to the U.S. population to create national estimates. Prevalence and service use rates from the ECA program are shown in Table 5.1–6. Over time, the analysis of data generated by the ECA program served to point out weaknesses in the DSM-III and its subsequent revisions, as well as provide valuable data for service planning and analytic studies. The high prevalence of diagnostic comorbidity among DSM-III disorders, particularly in the absence of DSM-III diagnostic hierarchies, was one of the first major issues uncovered by the analyses of ECA data. Surprisingly, a high prevalence of disorders previously thought to be rare, such as social phobia and obsessive-compulsive disorder, was found in the community; low rates of treatment for these and most other psychiatric disorders contributed to this mistaken assumption. The onset of many disorders was found to originate in childhood, contrary to much contemporary thinking that children were relatively protected from psychiatric disorders. Data from the ECA survey were instrumental in educating the general public as well as policymakers and legislators that mental disorders are real, prevalent in U.S. society, disabling, and grossly undertreated. Such basic efforts provided support, through an increasingly detailed series of reports released by NIMH, for parity of mental health insurance benefits with the benefits for other medical or surgical conditions and treatments. A similar purpose was served for the landmark *Surgeon General's Report on Mental Health,* published in 1999. More recently, the DIS clinical significance criteria data provided a crucial piece of information to evaluate the role of clinically significant distress and functional impairment in diagnosis and estimation of prevalence rates, as detailed below. Longitudinal follow-ups of the Baltimore ECA sample continued 16 and 22 years after the sample was originally drawn. Among the findings reported from these follow-ups are reports that major depressive episode is an independent risk factor for the development of hypertension and that cluster B personality disorders and traits are independent risk factors for the development of cardiovascular disease as well as cardiovascular mortality. Finally, the ECA program served as a stimulus for similar surveys in other locations, such as Puerto Rico and the Netherlands, and set the stage for subsequent U.S. and international surveys, such as the NCS and the WMH Survey Initiative.

Table 5.1–6. Effect of Clinical Significance Criteria on 1-Year Prevalence Rates of Mental Disorders in Adults, Age 18 to 54, ECA and NCS Surveys

	Prevalence, % (95% Confidence Interval)			
	Without Clinical Significance Criteria		With Clinical Significance Criteria	
Disorder	ECA	NCS	ECA	NCS
Simple phobia	[a]	8.6 (7.6, 9.6)	8.5 (7.9, 9.1)	4.4 (3.6, 5.2)
Social phobia	[a]	7.4 (6.6, 8.2)	2.0 (1.6, 2.4)	3.7 (3.1, 4.3)
Agoraphobia	[a]	3.7 (2.9, 4.5)	5.0 (4.4, 5.6)	2.2 (1.6, 2.8)
Any phobia	[a]	14.7 (13.3, 16.1)	11.4 (10.6, 12.2)	8.0 (7.2, 8.8)
Panic	[a]	2.2 (1.6, 2.8)	1.6 (1.2, 2.0)	1.7 (1.1, 2.3)
Generalized anxiety	NA	3.4 (2.8, 4.0)	NA	2.8 (2.2, 3.4)
PTSD	NA	3.6 (2.8, 4.4)	NA	3.6 (2.8, 4.4)
OCD	[a]	NA	2.3 (1.9, 2.7)	NA
Any anxiety	[a]	18.7 (17.1, 20.3)	13.3 (12.5, 14.1)	12.1 (10.7, 13.5)
Major depressive disorder	5.4 (4.8, 6.0)	8.9 (7.7, 10.1)	4.6 (4.0, 5.2)	5.4 (4.4, 6.4)
Bipolar I	1.2 (1.0, 1.4)	1.3 (0.9, 1.7)	0.6 (0.4, 0.8)	1.3 (0.9, 1.7)
Bipolar II	0.6 (0.4, 0.8)	0.2 (0.0, 0.4)	0.3 (0.1, 0.5)	0.2 (0.0, 0.4)
Dysthymia	[a]	2.5 (2.1, 2.9)	1.7 (1.3, 2.1)	1.8 (1.4, 2.2)
Any mood	10.4 (9.6, 11.2)	11.1 (9.7, 12.5)	5.7 (5.1, 6.3)	7.5 (6.3, 8.7)
Schizophrenia/NAP	1.3 (1.1, 1.5)	0.2 (0.0, 0.4)	1.3 (1.1, 1.5)	0.2 (0.0, 0.4)
Antisocial P.D.	2.0 (1.6, 2.4)	NA	2.0 (1.6, 2.4)	NA
Somatization	0.3 (0.1, 0.5)	NA	0.3 (0.1, 0.5)	NA
Anorexia nervosa	0.1 (0.1, 0.1)	NA	0.1 (0.1, 0.1)	NA
Severe cognitive impairment	1.3 (1.1, 1.5)	NA	0.2 (0.2, 0.2)	NA
Any nonsubstance use disorder	22.0 (21.0, 23.0)	23.4 (21.6, 25.2)	18.2 (17.2, 19.2)	15.4 (13.6, 17.2)
Any alcohol disorder	9.1 (8.3, 9.9)	9.9 (8.9, 10.9)	8.9 (8.3, 9.5)	6.5 (5.7, 7.3)

[a] Clinical significance for the anxiety disorders and dysthymia was assessed at the symptom level in the ECA, and rates for syndromes without clinical significance could not be calculated.

NA, not assessed.

The NCS and Associated Studies. The *National Comorbidity Survey* (NCS) was an NIMH and National Institute on Drug Abuse (NIDA)-sponsored survey designed to study the comorbidity of DSM-III-R substance use disorders and other mental disorders. Unlike the ECA, it was a nationally representative household survey with 8,098 respondents. It was fielded from 1990 to 1992. Because of the relatively low prevalence of substance use disorders in older populations, the age of subjects sampled for the NCS was capped at 54 years to maximize its analytic goals; to minimize recall bias of early-onset disorders, the lower age range of the survey was 15 years. In addition to measuring a wide range of psychiatric disorders with the UM-CIDI and mental health service use, a plethora of other domains were included in the NCS survey, such as human immunodeficiency virus (HIV) risk behaviors, personality constructs, and social life. The initially published prevalence rates of mental disorders from the NCS were generally higher than those previously published from the ECA program, leading to intense scrutiny of both surveys and uncertainty as to how to use the NCS results for health service policy and planning. In particular, it was not evident that the prevalence estimates of the NCS reflected a true, substantial increase in the rates of mental disorders in the United States in the decade since the initiation of the ECA program. Nor was it evident that the ECA substantially underestimated the prevalence rates of mental disorders; indeed, the rates of disorders reported by the ECA program were themselves felt to be nonconservative. Methodologic and diagnostic differences in the two surveys were suspected, at least in part, to underlie the differences in prevalence rates. First, there were some differences between the diagnostic criteria in DSM-III and DSM-III-R, which were reflected in the respective diagnostic instruments and could affect prevalence rates. Second, differences in the age ranges of the respondents in the two surveys could affect prevalence rates; although few previous comparison data were available for the prevalence of mental disorders in adolescents aged 15 to 17 years sampled in the NCS, it had been documented that in epidemiologic surveys, prevalence rates of mental disorders declined with age and were particularly low in the older adults. Third, the effects of several innovations in the UM-CIDI, such as grouping of stem questions and the commitment question, were unknown but potentially could increase rates of positive responses in the NCS. Finally, it was recognized that the clinical significance questions in the NCS were not used to determine prevalence rates and were used inconsistently in the ECA prevalence estimates. In a study that aimed to reconcile the age range differences and apply the unused clinical significance questions, the overall prevalence estimates of the ECA were reduced by about 17%, and estimates of the NCS were reduced by about one-third. As a result, the estimates of the two surveys were brought closer together (see Table 5.1–6).

Several surveys related to the NCS have subsequently been carried out. The NSC-R surveyed another national sample from 2001 to 2003. The sample size was 9,282. This survey allowed comparisons of rates of mental disorders and service use in the decade since the original NCS survey in a repeated cross-sectional design. Many aspects of the NCS survey instrument were kept intact for the NCS-R to promote these comparisons. However, based on knowledge gained in the intervening years, new components were also added to the NCS-R, as described in the section on the WMH-CIDI above. One-year prevalence rates from the NCS-R are found in Table 5.1–7, and rates of service use are found in Table 5.1–8. Although the NCS-R permitted another cross-sectional estimate for the U.S. population, the NCS-2, by contrast, attempted to reinterview all respondents in the original NCS survey. The NCS-2 was conducted from 2001 to 2002. The longitudinal aspect of the survey has allowed investigators to examine risk factors for the new onset of disorders and to study the course of illness in persons who did have disorders in the original NCS survey. Several articles have been published using the NCS/NCS-2 data sets. These include studies of risk factors for suicide-related outcomes, mental disorders as risk factors for substance use disorders, and the role of baseline mental disorder severity in later clinical outcomes.

In the 1990s, increasing attention began to be focused on disparities in health status between the white population and racial and ethnic minority populations in the United States. These disparities appeared across diseases and covered not only differences in prevalence but also differences in the use of health services to treat these conditions. Three nationally representative surveys connected with the NCS-R were conducted to further explore these issues for mental disorders. The *National Survey of American Life* (NSAL) interviewed 3,570 African American subjects, 1,623 African-Caribbean immigrants, and 1,006 non-Hispanic white subjects. The National Latino and Asian American Study (NLAAS) conducted surveys of four Latino groups (Cuban, Mexican, Puerto Rican, and “other Latino”) with a sample size of 2,554, four Asian groups (Chinese, Filipino, Vietnamese, and “other Asian”) with a sample size of 2,095, and a small control group of non-Hispanic whites. The surveys used the WMH-CIDI, with translations into Spanish, Chinese, Vietnamese, and Tagalog for respondents who preferred to take the interview in those languages. Many articles have been published from these data sets on a variety of topics, although 12-month prevalence and service use rates for specific disorders in specific ethnic/racial groups were published in a piecemeal fashion.

Table 5.1–7.

1-Year Prevalence Rates of DSM-IV Mental Disorders in Adults, NCS-R and NESARC and NESARC-III Surveys

Disorder	**Prevalence, % (SE)**		
	NCS-R	**NESARC**[a]	**NESARC-III**[b]
Specific phobia	8.7 (0.4)	7.1 (0.3)	4.6 (0.2)
Social phobia	6.8 (0.3)	2.8 (0.1)	2.9
Agoraphobia w/o panic	0.8 (0.1)		0.9 (0.1)
Panic	2.7 (0.2)		2.7 (0.1)
Panic w/agoraphobia		0.6 (0.1)	
Panic w/o agoraphobia		1.6 (0.1)	
Generalized anxiety	3.1 (0.2)	2.1 (0.1)	4.4 (0.2)
PTSD	3.5 (0.3)		4.7
OCD	1.0 (0.3)		
Any anxiety	18.1 (0.7)	10.4 (0.3)	12.7
Major depressive disorder	6.7 (0.3)	7.1 (0.2)	15.1 (0.3)
Bipolar I or II	2.6 (0.2)		1.4
Mania		1.7 (0.1)	
Hypomania		1.2 (0.1)	
Dysthymia	1.5 (0.1)	1.8 (0.1)	3.2 (0.1)
Any mood	9.5 (0.4)	9.2 (0.2)	12.8
Any impulse control disorder	8.9 (0.5)		
Alcohol abuse	3.1 (0.3)	4.7 (0.2)	
Alcohol dependence	1.3 (0.2)	3.8 (0.1)	
Any alcohol disorder		8.5 (0.2)	13.9
Drug abuse	1.4 (0.1)	1.4 (0.1)	
Drug dependence	0.4 (0.1)	0.6 (0.1)	
Any drug use disorder		2.0 (0.1)	3.9
Any substance use disorder	3.8 (0.3)	9.4 (0.3)	3.9

Any disorder	26.2 (0.8)	29.0

[a] Rates for NESARC mood and anxiety disorders exclude substance-induced disorders.

[b] NESARC-III data based on Simpson et al., 2019; Olfson et al., 2019; Grant 2016 (some of the sources did not provide SE data).

PTSD, post-traumatic stress disorder; OCD, obsessive-compulsive disorder.

The National Survey on Drug Use and Health (NSDUH). The *National Survey on Drug Use and Health* (NSDUH) provides up-to-date information on tobacco, alcohol, drug use, mental health, and other health-related issues in the United States. The survey is designed as a face-to-face household interview targeting civilian, noninstitutionalized populations 12 years or older residing in the United States. The NSDUH survey began in 1971 and is conducted annually in all 50 states and the District of Columbia. In 2019, about 50,731 interviews with adults aged 18 or older were obtained. Diagnoses in the NSDUH survey are currently based on either DSM-IV or DSM-5 criteria depending on the disorder. Table 5.1–9 shows the substance use percentage in 2019 based on the NSDUH. The survey uses various instruments to collect data such as the Structured Clinical Interview for DSM-5—Research Version, the World Health Organization Disability Assessment Schedule (WHODAS 2.0), Kessler-6 Psychological Distress Scale (K6), the Nicotine Dependence Syndrome Scale (NDSS), and the Fagerstrom Test of Nicotine Dependence (FTND) among others.

Over the years, DSM III, III-R, IV, and 5 criteria were used to describe various mental health and substance use disorders. The NSDUH publishes reports annually with past month or past year estimates of substance use and related treatment presented separately for people aged 12 or older, adolescents, and adults. Additionally, estimates of mental health issues and mental health service use are presented for adolescents aged 12 to 17 and adults aged 18 or older.

Alcohol	21.2	72.0	69.1

NE, not estimated.

Data from the Substance Abuse and Mental Health Services Administration. Key substance use and mental health indicators in the United States: Results from the 2019 National Survey on Drug Use and Health (HHS Publication No. PEP20-07-01-001, NSDUH Series H-55). Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration; 2020. https://www.samhsa.gov/data/

World Mental Health Initiative. The paucity and noncomparability of epidemiologic data on mental disorders and their consequences in many countries, particularly in developing nations, was a hindrance to the WHO's Global Burden of Disease study (described below). For this reason, the *World Mental Health* (WMH) *Initiative* was conceived by the WHO to increase precision in future estimates of the societal burden of mental disorders and, in turn, provide a more solid basis for mental health service planning and delivery of effective interventions. The initiative aimed to study the prevalence of mental disorders, their consequences in terms of disabilities and social disadvantages, and patterns of service use for mental disorders. Twenty-nine countries participated in the WMH Initiative, representing all WHO regions (6 countries in the Pan-American region including the NCS-R in the United States, 2 in Africa, 3 in the Eastern Mediterranean, 13 in Europe including Israel, 1 in Southeast Asia, and 5 in the Western Pacific). Some countries chose to perform national surveys, and others chose to sample from smaller geographical units in their countries. All surveys did, however, use multistage household probability sampling to ensure that their results could be generalized to their target populations. In all, over 160,000 respondents were sampled worldwide. The WMH-CIDI was the diagnostic instrument, and both DSM-IV and ICD-10 diagnoses were assessed. To increase comparability in implementation, instrument translations were done according to standard WHO protocols. Interviewers for each country were trained centrally with the same documents and protocols. Informed consent and institutional review board approvals were required. The 12-month prevalence of mental disorders in an initial group of WMH-participating countries is shown in Table 5.1–10. The wide range of rates across countries was suggested to be due to variations in symptom expressions in some countries. The validity of the WMH-CIDI diagnoses was not tested at all sites, so the ability of the instrument to detect specific diagnoses in diverse cultures is uncertain. Idioms of distress and conceptualizations of psychiatric symptoms may vary across cultures, reducing the validity of a translated common measurement instrument. It was also suggested that variations in the translation, implementation, and quality control across sites may account for the prevalence differences. Countries that had the lowest disorder prevalence also had the highest proportion of cases classified as “subthreshold” which did not meet the criteria for DSM-IV/CIDI disorders. Finally, it is not possible to adequately control for the large differences in potentially relevant social factors (e.g., income, education) between countries in the WMH surveys, and these differences, when uncontrolled, could account for some portion of the prevalence differences.

Table 5.1–10.
12-Month Prevalence Estimates of DSM-IV/CIDI Disorders in the W M H Surveys[a,b]

	Any Anxiety Disorder	Any Mood Disorder	Any Externalizing Disorder	Any Substance Disorder	Any Disorder

Japan	4.2 (0.6)[c]	2.5 (0.4)	0.2 (0.1)[g,h,i]	1.2 (0.4)	7.4 (0.9)
New Zealand	15.0 (0.5)[c]	8.0 (0.4)	– –[f,g,h,i]	3.5 (0.2)	20.7 (0.6)

[a] Anxiety disorders include agoraphobia, adult separation anxiety disorder, generalized anxiety disorder, panic disorder, post-traumatic stress disorder, social phobia, and specific phobia. Mood disorders include bipolar disorders, dysthymia, and major depressive disorder. Impulse-control disorders include intermittent explosive disorder and reported persistence in the past 12 months of symptoms of three child-adolescent disorders (attention-deficit/hyperactivity disorder, conduct disorder, and oppositional-defiant disorder). Substance disorders include alcohol or drug abuse with or without dependence. In the case of substance dependence, respondents who met full criteria at some time in their life and who continue to have any symptoms are considered to have 12-month dependence even if they currently do not meet full criteria for the disorder. Organic exclusions were made as specified in the *Diagnostic and Statistical Manual of Mental Health Disorders, Fourth Edition.*

[b] Impulse disorders restricted to age ≤39 (China, Ukraine, Nigeria) or to age ≤ 44 (all other countries).

[c] Adult Separation Anxiety Disorder was not assessed.

[d] Specific Phobia was not assessed.

[e] Bipolar disorders were not assessed.

[f] Intermittent explosive disorder was not assessed.

[g] Attention-deficit/hyperactivity disorder was not assessed.

[h] Conduct disorder was not assessed.

[i] The Oppositional-defiant disorder was not assessed.

[j] Only alcohol abuse with or without dependence was assessed. No assessment was made of other drug abuse with or without dependence.

[k] People's Republic of China.

National Epidemiologic Survey on Alcohol and Related Conditions. The National Institute of Alcohol Abuse and Alcoholism's *National Epidemiologic Survey on Alcohol and Related Conditions* (NESARC) is a series of population-based surveys of alcohol use disorders and other substance use and mental disorders in the United States. Among its goals were to provide prevalence and incidence rates of alcohol-related disorders and associated disabilities; examine comorbidity patterns with other mental disorders, including other substance use disorders; document the natural history of alcohol-related disorders and disabilities; examine service use rates and patterns and barriers to care; and attempt to elucidate and differentiate "alcohol-induced" physical and mental disorders from "independent" disorders. The NESARC has been fielded three times. The first survey, with an unprecedented sample size of 43,093, was fielded from 2001 to 2002. This sample was nationally representative of the adult household population of the United States, also including noninstitutional group quarters such as boarding and rooming houses, nontransient hotels, shelters, worker housing, college quarters, and group homes. The second survey aimed to reinterview all first-wave respondents and was fielded from 2004 to 2005. A total of 34,653 interviews were completed, amounting to a response rate of 86.7%. The data from the second wave of the survey has allowed estimation of incidence rates and risk factors for the development of alcohol, drug, and other mental disorders, as well as examination of the course and outcome of treated and untreated mental and substance use disorders. One-year prevalence rates from the first NESARC survey are listed in Table 5.1–7. One-year incidence rates based on the first two surveys are listed in Table 5.1–11. NESARC-III was fielded from 2012 to 2013. The target population was the U.S. civilian, noninstitutionalized population ages 18 and over, with an oversampling of Black, Hispanic, and Asian populations. The total sample size was 36,309, representing an overall response rate of 60.1%. Genetic data from the NESARC-III that were collected from about 23,000 survey participants are available for researchers.

Table 5.1–11.

12-Month Incidence of DSM-IV Psychiatric Disorders, NESARC Wave 2

DSM-IV Disorder	Unweighted Number of Respondents at Risk	Unweighted Number of 12-Month Incident Cases	Weighted Annual Incidence per 100 Person-Years
Alcohol use disorder[a]	23,713	363	1.66 (0.11)[b]
Alcohol abuse	24,291	233	1.03 (0.10)
Alcohol dependence	30,220	481	1.72 (0.09)
Any drug use disorder[a]	30,830	89	0.31 (0.04)
Any drug abuse	30,887	75	0.28 (0.04)
Any drug dependence	33,639	101	0.32 (0.04)
Any mood disorder[a]	26,867	666	2.24 (0.12)
Major depressive disorder	28,859	489	1.52 (0.09)
Bipolar I	32,990	189	0.53 (0.05)
Bipolar II	34,045	74	0.21 (0.03)
Any anxiety disorder[a]	26,179	452	1.58 (0.09)
Any panic disorder	32,302	224	0.62 (0.05)
Social phobia	32,352	112	0.32 (0.04)
Specific phobia	29,502	147	0.44 (0.05)
Generalized anxiety	32,361	390	1.13 (0.08)

[a] Because the population at risk for each aggregate disorder category excludes all respondents with prior lifetime histories of any disorder in that category, the

denominator of the incidence rate is invariably smaller than the denominator for any component disorder. For the same reason, and because individuals can become incident cases of more than one disorder in each category in the same time period, the numerator for the aggregate rate is not a simple sum of the number of incident cases across the specific disorders.

[b]Numbers in parentheses are standard errors.

Adapted from Grant BF, Goldstein RB, Chou SP, et al. Sociodemographic and psychopathologic predictors of first incidence of DSM-IV substance use, mood, and anxiety disorders: results from the Wave 2 National Epidemiologic Survey on Alcohol and Related Conditions. *Mol Psychiatry.* 2009;14(11):1051–1066, with permission of Springer Nature.

Surveys of Mental Disorders in Children and Adolescents

Concerted research efforts on child and adolescent mental disorders started later than on adult disorders, and the knowledge base is correspondingly smaller for epidemiologic and treatment studies alike. The reasons for this are multifaceted, but as noted above, mental disorders in these populations were considered to be relatively rare until the ECA and other studies in the 1980s revealed much younger ages of onset for common mental disorders than was previously assumed. Diagnostic criteria for children and adolescents were widely criticized by clinicians and researchers for being difficult to operationalize and not reflecting developmental considerations and clinical reality, deficiencies that the DSM-5 attempted to remedy. In addition, the paucity of treatment services for children and adolescents hid what was later found to be a high prevalence of untreated mental disorders. However, interest in the diagnosis and the epidemiology of child and adolescent mental disorders has increased since the fielding of the ECA program. In fact, researchers have been able to take advantage of, and contribute to, advances in diagnostic criteria and research methods since the DSM-III and the ECA by developing sophisticated diagnostic instruments and study designs. Unfortunately, no global epidemiologic studies have been fielded in child and adolescent populations. However, several national surveys and datasets include information on children’s mental health as described below.

Methods for the Epidemiology of Child and Adolescent Mental Disorders. In the wake of the successes of the ECA program, the need to stimulate the field of child and adolescent psychiatric epidemiology with a “child ECA” was recognized as a crucial next step by the NIMH. Also recognized, however, was that diagnosing children and adolescents in community settings would require different methods than were used for adults in the ECA. It was assumed that depending on the developmental level of the children surveyed, a parent or primary caregiver might be needed as an informant on diagnostic and service use variables, and other informants such as teachers might give valuable additional information. A major issue to be clarified was how to gather this information in a large-scale survey and then how to best combine these multiple-source reports to arrive at reliable and valid diagnoses. The reliability and validity of the available diagnostic instruments also needed to be confirmed. Developing and evaluating assessments of disability and service use also needed to be addressed. NIMH set up a two-phase program, the first phase of which was a methodologic evaluation addressing the issues named above, and the second phase a full multisite survey, the “child ECA.” The MECA survey was a cooperative agreement between the NIMH and four academically based sites in New York City, New Haven, Atlanta, and San Juan, which was funded to address these methodologic issues in child and adolescent psychiatric epidemiology. The MECA surveys included children ages 9 to 17 years. The NIMH DISC, version 2.3, was used as the core diagnostic assessment instrument for DSM-III-R disorders, and an instrument to assess service use, sociodemographic factors, and potential risk and protective factors was developed. The CGAS and the Columbia Impairment Scale were included in the survey to assess disability. Only parent and child reports were obtained, mainly due to a lack of funds to obtain other informant reports. Data collection was completed in 1992, with 1,285 parent–child pairs being interviewed. Reliability and validity tests were set up to assess the DISC’s performance with both clinicians and lay interviewers. The DISC 2.3 was found to have acceptable reliability and criterion validity, and several reports on methodology, diagnosis, disability, and service use were published. Despite the successes of the MECA survey, the anticipated “child ECA” was never fielded. The results of the longitudinal Great Smoky Mountains Study have also provided extremely valuable descriptive and analytic data in a sample that has been followed longitudinally, but this study’s sampling was limited to a geographical area in North Carolina.

National Comorbidity Survey Replication Adolescent Supplement. The National Comorbidity Survey Replication Adolescent Supplement (NCS-A) was a supplemental survey to the NCS-R, conducted from 2001 to 2004. As such, it sampled youth ages 13 to 17 years from the households selected for the NCS-R and from a representative sample of schools located in the counties where the household surveys were conducted. The final sample size from households was 904, with an 86.8% response rate. From the 320 schools sampled, 9,244 youth were selected, with an 82.6% response rate. The youth were administered a modified version of the CIDI that had alterations in phrasing and examples to make it more appropriate to the respondents' language level and life experiences. Some disorders were dropped from the CIDI for this population, such as pathologic gambling, obsessive-compulsive disorder, and psychotic disorders. A parent or adult surrogate was given a self-administered assessment but not directly interviewed. This assessment was relatively brief, covering the youth's symptoms in categories for which adult reports of psychopathology were felt to be particularly important for making a diagnosis (major depressive episode, dysthymia, separation anxiety disorder, attention-deficit/hyperactivity disorder, conduct disorder, and oppositional-defiant disorder). The adult also filled out the Strengths and Difficulties Questionnaire. NCS-A data efforts ceased in 2002. Publications using NCS-A data have been slowly accumulating since the initial publication of findings in 2009. The NCS-A data showed that the 1-year prevalence of any mental, behavioral, or substance use disorder in the adolescent population was 40.2%, with estimates ranging from 8.3% for any substance use disorder to 24.9 for any anxiety disorder.

Youth Risk Behavior Surveillance System (YRBSS). The YRBSS is conducted to identify leading causes of death, disability, and social problems among youth and adults in the United States. The survey is conducted among 9th through 12th-grade students and asks questions about behaviors that contribute to unintentional injury and violence, substance use, and sexual behaviors related to unintended pregnancy and sexually transmitted infections. The survey has collected responses from more than 4.9 million high school students since 1991. Although this survey does not specifically examine mental disorders, analysis of co-occurring health behaviors such as violence, substance use, and unsafe sexual behaviors provide information on risk factors associated with mental disorders. The YRBS questionnaire is 87-item long and is administered every 2 years.

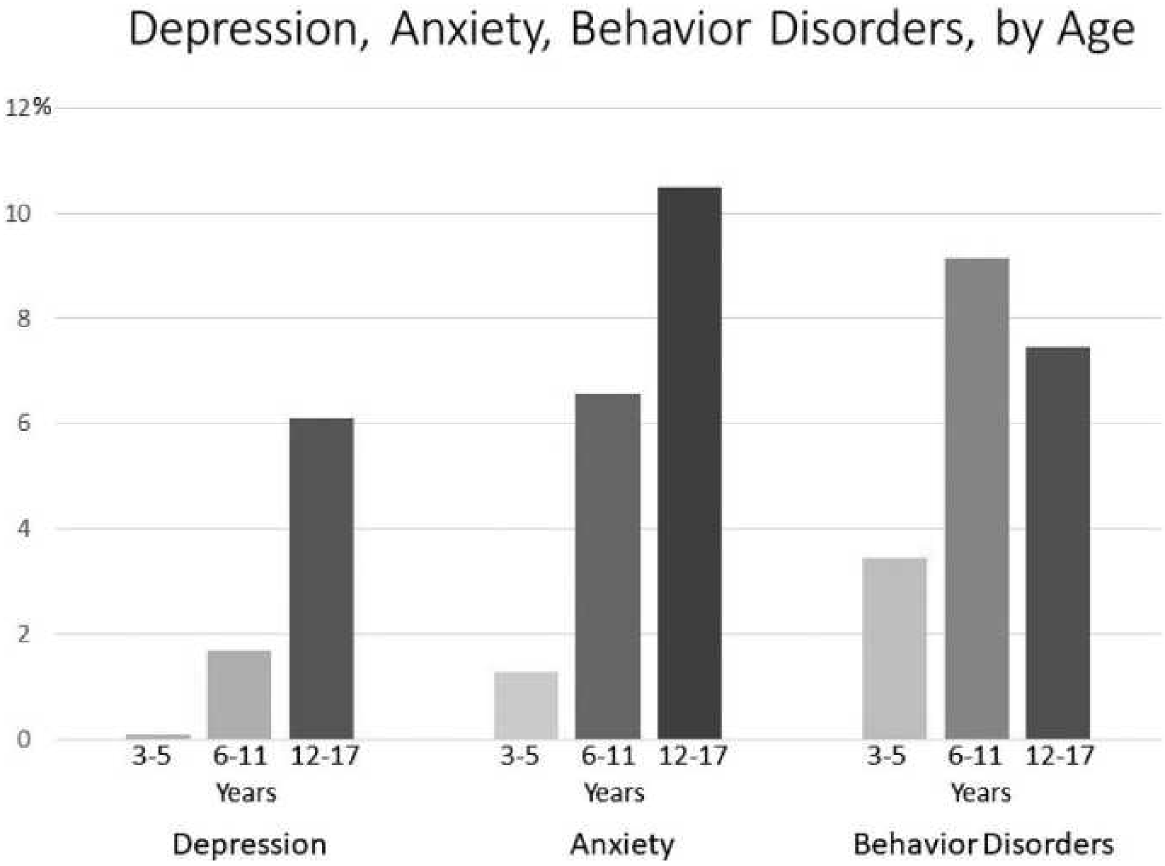

FIGURE 5.1–1. Percentage of children with mental health conditions per age group and disorder categories. (Based on Reprinted from Centers for Disease Control and Prevention. Data and Statistics on Children's Mental Health. https://www.cdc.gov/childrensmentalhealth/data.html.)

The National Survey of Children's Health. The *National Survey of Children's Health* NSCH survey provides data on children's physical and mental health along with access to care, education, and psychosocial context. The survey contains separate questionnaires for the age groups 0 to 5, 6 to 11, and 12 to 17 years and asks about the child's history of mental disorders.

Overall, aggregated data from children's mental health show that anxiety and depression are more common among older subgroups, while behavior problems are more common among the 6 to 11 years age group compared to the other two subgroups, as shown in Figure 5.1–1.

In addition to the surveys mentioned above, there are other important national health surveys that include a mental distress measure such as the Behavioral Risk Factor Surveillance System (BRFSS), which collects information on health risk behaviors, preventative practices, and healthcare access. The *National Health and Nutrition Examination Survey* (NHANES) collected data on depression, anxiety, concerns associated with mental health and substance abuse, and mental health service use and need. The *National Health Interview Survey* (NHIS) collects data on both adult and children's mental health and mental disorders. The *National Survey of the Diagnosis and Treatment of ADHD and Tourette Syndrome* (NS-DATA) collects information about children 2 to 15 years old in 2011 to 2012 who had ever been diagnosed with attention deficit hyperactivity disorder and/or Tourette syndrome to understand diagnostic practices, level of impairment, and treatments for this group of children. More information on these surveys can be accessed through the Centers for Disease Control and Prevention page: https://www.cdc.gov/mentalhealth/data_publications/index.htm

WHO Global Burden of Disease Study

The innovative *Global Burden of Disease* (GBD) studies are perhaps the best examples of the use of population-based epidemiologic surveys to serve the needs of public health policy and planning. There have been six GBD studies, the first published in 1996 and sponsored by the WHO and the World Bank, and subsequent ones (GBD 2010, 2013, 2015, 2017, and 2019) sponsored by the Bill and Melinda Gates Foundation. The GBD studies recognized that the consequences of a disease include not only death but also disability, and the impact of disability should be quantified and factored into any estimates of disease burden. By taking disability into account, these studies served to draw attention to chronic diseases, including mental and substance use disorders, which may ultimately cause premature death but often cause significant societal burden through reduced role functioning. *Disability-adjusted life years* (DALYs) were used to estimate the burden of disease. DALYs represent the sum of years of life lost to premature death (YLL) and years lived with a disability of a specified severity and duration due to the condition (YLD). One DALY represents 1 year of healthy life lost. GBD 1990 showed that five of the top ten causes of disability fell under the neuropsychiatric disorder category–a grouping that included mental and substance use disorders with neurologic disorders. GBD 2010 was a more ambitious project compared to the first study, expanding the number of health conditions, including mental and substance use disorders. Compared to the 1990 study, the 2010 study added six more categories: anxiety disorders, eating disorders, pervasive developmental disorders, childhood behavior disorders, dysthymia, and bipolar disorder subtypes. Substance use disorder was expanded to include burdens for alcohol use disorders and illicit drug use disorders. GBD 2010 also added new computations that accounted for the burden of mental and substance use disorders as risk factors for other disorders. Four risk factors were quantified: major depressive disorder as a risk factor for ischemic heart disease; cannabis use as a risk factor for schizophrenia; major depressive disorder, bipolar disorder, anxiety disorder, anorexia nervosa, schizophrenia, cocaine dependence, amphetamine dependence, and opioid dependence as risk factors for suicide; and injection drug use as a risk factor for hepatitis B and C and HIV.

Table 5.1–12.
Proportion of YLDs, YLLs, and DALYs Explained by the 10 Leading Causes of Total Burden in 2019

	Proportion of Total DALYs (95% UI)	Proportion of Total YLDs (95% UI)	Proportion of Total YLLs (95% UI)
Cardiovascular diseases	15.5% (14.1–16.9)	4.0% (3.4–4.5)	21.4% (20.0—22.6)
Neoplasms	9.9% (9.0-11.0)	0.9% (0.8–1.0)	14.5% (13.6–15.3)
Maternal and neonatal disorders	7.8% (6.8–8.9)	2.3% (1.8–3.0)	10.6% (9.7–11.7)
Respiratory infections and tuberculosis	6.0% (5.5–6.6)	1.5% (1.3–1.8)	8.3% (7.8–8.9)
Other noncommunicable diseases	6.0% (5.3–6.9)	10.1% (8.6–12.1)	3.9% (3.4–4.5)
Musculoskeletal disorders	5.9% (4.6–7.3)	17.1% (14.9–19.8)	0.2% (0.1–0.2)
Mental disorders	4.9% (3.9–6.1)	14.6% (12.2–16.8)	0.0% (0.0–0.0)
Diabetes and kidney diseases	4.4% (4.2–4.7)	5.3% (4.7–5.9)	4.0% (3.8–4.2)
Chronic respiratory diseases	4.1% (3.7–4.4)	3.8% (3.2–4.4)	4.2% (3.8–4.6)
Unintentional injuries	4.1% (3.7–4.4)	4.4% (3.8–5.1)	3.9% (3.4–4.3)

The most recent GBD study (GBD 2019) analyzed 286 causes of death, 369 diseases, and injuries in 204 countries and territories. To calculate the global burden of mental and substance use disorders, the study investigators performed extensive literature searches for data on prevalence, incidence, remission and duration, and all-cause excess mortality. Publications were required to use DSM or ICD diagnostic criteria, to employ representative sampling of a community, and to provide sufficient information on study methods and sample characteristics. Prevalence was required to be reported in a current (point or past month) or past-year time frame.

Table 5.1–13. Proportion of YLDs (A), YLLs (B), and DALYs (C) Explained by Each Mental and Substance Use Disorder Group in 2019

	YLDs (95% UI)	YLLs (95% UI)	DALYs (95% UI)
Depressive disorders	31.6% (22.2–43.0)		29.2% (20.5–39.8)
Anxiety disorders	19.3% (13.4–26.5)		17.9% (12.4–24.5)
Drug use disorders	8.2% (5.7–10.9)	48.3% (46.5–50.8)	11.3% (8.9–13.7)
Alcohol use disorders	7.2% (4.9–10.3)	51.5% (44.2–55.0)	10.6% (8.4–13.4)
Schizophrenia	10.2% (7.4–13.0)		9.4% (6.9–12.0)
Other mental disorders	5.8% (3.8–8.8)		5.4% (3.5–8.2)
Bipolar disorder	5.7% (3.5–8.8)		5.3% (3.2–8.1)
Conduct disorder	3.3% (1.8–5.1)		3.0% (1.7–4.8)
Idiopathic developmental intellectual disability	3.0% (1.6–4.9)		2.7% (1.4–4.5)
Autism spectrum disorders	2.9% (1.9–4.2)		2.7% (1.8–3.9)
Eating disorders	2.0% (1.2–2.9)	0.1% (0.1–0.2)	1.8% (1.1–2.7)
Attention-deficit/hyperactivity disorder	0.7% (0.4–1.2)		0.6% (0.4–1.1)

Data are % (95% UI). DALYs, disability-adjusted life years; YLDs, years lived with a disability; YLLs, years of life lost.

Institute for Health Metrics Evaluation. Used with permission. All rights reserved. http://ghdx.healthdata.org/gbd-results-tool.

Tables 5.1–12 and 5.1–13 show some of the main results of GBD 2019. Cardiovascular diseases, neoplasms, and maternal and neonatal disorders were the major causes of disease burden worldwide. However, mental disorders were a major source of burden as well, accounting for roughly 5% of the total disease burden. Looking solely at mental disorders, the leading sources of DALYs were depressive disorders, followed by anxiety disorders, drug and alcohol use disorders, schizophrenia, and other mental disorders. This pattern was also seen for YLDs. Alcohol and drug use disorders accounted for the majority of YLLs; data were sufficient to attribute only three disorders as a cause of death. Countries with the highest DALY rates for mental disorders were Western Europe, sub-Saharan Africa, North Africa, and the Middle East. Locations in Asia were among those with the lowest DALY rates. Not surprisingly, the largest number of acceptable data sources were from high-income regions indicating the need for reviewing the cross-cultural applicability of case definition and data collection methods. Overall, the global distribution and burden of mental disorders have increased steadily since 1990, except for alcohol use disorder (Fig. 5.1–2).

EMERGING ISSUES

Coronavirus Disease-2019 Pandemic (COVID-19)

On March 11, 2020, the World Health Organization declared COVID-19 a global pandemic, leading many countries to close their borders, forcing quarantine, and imposing strict measures (social distancing) to curb the spread of the deadly virus. These unprecedented measures led to disruptions in daily functioning, physical activity, sleep, as well as mental health. In a meta-analysis of published literature, there was a higher reported prevalence of suicide during the pandemic. The study observed that the main risk for suicidal ideations for frontline medical workers included low social support, high physical and mental exhaustion, and poorer self-reported physical health, while for the general population, the risk factors included sleep disturbances, exhaustion, loneliness, and mental health difficulties. In other literature reviews, there was a substantial increase in the prevalence and burden of major depressive disorder and anxiety disorders as well as worsening of eating disorder psychopathology as a result of the COVID-19 pandemic. Other studies reported that burnout, post-traumatic stress disorder, and violence have increased with the pandemic. A study conducted on over 8,000 families between March 2020 and March 2021 in the United Kingdom showed a clear increase in parent-reported symptoms of behavioral and attentional difficulties among children and adolescents during the time of lockdown. In a sample of children and youth, it was found that exposure to greater pandemic-related stressors led to higher levels of internalizing and externalizing psychopathology. This effect was especially prominent at the time of the lockdown through 6 months after. However, having a structured daily routine, low passive screen time use, low pandemic-news consumption, spending more time in nature as well as a healthy sleep routine were associated with better mental health outcomes.

These reports are preliminary since a longer period of time is needed to collect more data and observe the trends concerning the COVID-19 pandemic and its impact on mental health.

▲ 5.2 Statistics and Experimental Design

EUGENE LASKA, PH.D., CAROLE E. SIEGEL, PH.D., AND ISAAC GALATZER-LEVY, PH.D.

Jerry Cornfield declared that statistics is the bedfellow of the sciences in his presidential address to the American Statistical Association in 1974. Even a casual reader of articles that appear in the medical and psychiatric literature becomes aware of arcane terms such as chi-square and analysis of variance (ANOVA) and *P* values. The lexicon of statistics is now part of the common parlance of editors, reviewers, and authors, so to appraise and appreciate a scientific article, it is incumbent on the reader to have some familiarity with the lingua franca. Of course, it may be argued, the user of a computer need not understand the bits and bytes and operating system that drive the processor to use it, so why can't the reader simply accept that the referees and editors have done their jobs? Indeed, why can't the reader just peruse the abstract and the discussion section and be done with it? Well, truth be told, he or she can. A word processor can be used successfully even by one with limited computer skills. A scientific report can be skimmed to obtain the essence of its message without needing to appreciate the nuances of the methods utilized. But that strategy will not enable an independent view of the strength of the evidence nor of the credibility of the findings. The reputation of the author and the journal may provide some comfort, and perhaps in reports related only peripherally to the reader's interests, that is all that is required. But at least in one's own field of expertise, a full understanding of the techniques used to obtain the results and to reach the conclusions should be accessible. If the reader wants to truly understand the material, then at least a rudimentary understanding of statistical concepts is necessary.

So, what are the must-know elements of statistics? It is hard to say. It depends on the area of science or therapeutics that is of interest. The discipline of statistics has become so vast that few, if any, professionals can pretend to be an expert in all of its parts. But a psychiatrist should have at least a basic understanding of the rudiments. This chapter will not try to replicate what countless articles, books, and streaming-abbreviated introductory courses do. The basic ideas are described without any assumptions about the mathematical skill level of the reader in many elementary texts and chapters. It is assumed that the reader already has some familiarity with the basic concepts, but nevertheless, this chapter begins with a very brief review of some elementary statistical ideas. We also introduce some topics in machine learning. The remainder of the chapter discusses some of the many topics in statistics selected in the hope that they will increase the capability of a reader to make independent judgments and interpretations about the articles that he or she reads. Necessarily, the presentations are incomplete, the choice of topics is somewhat arbitrary, and there are many other topics that could have been included in this chapter. It is the authors' hope that this presentation will stimulate further study of statistical methods, particularly by individuals interested in psychiatric research. Although the authors have strived to keep technical details to a minimum, occasionally, some complexities are unavoidable.

BASIC IDEAS

In this section, the notions of elementary probability theory are reviewed, and the concepts of a random variable, measures of central tendency, and a measure of dispersion are introduced. To describe the joint behavior of two random variables, the ideas of statistical independence, covariance, and correlation are necessary to enable the introduction of a multivariate distribution.

Probability Theory

The mathematical foundation on which statistical methods are built is probability theory. This theory considers a situation in which the outcomes are random events. The set of all possible simple outcomes is called the *sample space*. For example, throwing a die once gives rise to a sample space containing six elements: 1, 2, 3, 4, 5, 6. A random variable is a mapping of the sample space onto the real line. It is usually denoted by an uppercase Latin letter such as X, and an actual outcome is usually denoted by its corresponding lowercase letter x. Thus, X is the random outcome of the face value resulting from the roll of the die, and $x = 6$ is an observed outcome. Corresponding to each *simple* outcome is a number greater than or equal to zero representing the probability of the outcome. It is defined as the long-run relative frequency of the event. For a fair die, the probability that it lands 6, written $\mathrm{P}(X = 6)$, is 1/6. The sum of the probabilities over all simple outcomes in the sample space is 1. The assignment of a probability to a simple outcome automatically determines the probability of all subsets of the sample space. For example, the probability that the outcome of the roll of the die is an odd number is $\mathrm{P}(X = 1) + \mathrm{P}(X = 3) + \mathrm{P}(X = 5) = 1/2$.

Probability Density Functions

Characterization of the random nature of an experiment is provided by the chance of observing a particular value x. If there are only a finite number of possible outcomes, the probability of each event x, $P(X = x)$ as a function of x, is called a probability density function (PDF). If the range of outcome values includes all values in an interval, the *continuous case*, the PDF, generically denoted by $\mathrm{f}(x)$, has a slightly different meaning. This is because the probability of observing any particular single value of x, possibly with a finite (countable) number of exceptions, is 0. In this case, the area under the density curve in the interval, the integral of $\mathrm{f}(x)$ over the interval, is equal to the probability that an outcome falls in that interval. The *cumulative distribution function*, frequently represented by $\mathrm{F}(x)$, is the probability that the random variable takes a value less than or equal to x. It is obtained in the discrete case by summing the probabilities of all possible outcomes that are less than or equal to x and in the continuous case by integrating the PDF from minus infinity to x. All probabilities must be nonnegative, and their sum over all possible events, or in the continuous case, the integral over the sample space, must be 1. Therefore, as x goes to infinity, $F(x)$ goes to 1. The frequentist interpretation of probability is that in the long run, the fraction of times that the outcome x is observed (or that x falls in a specific interval $[a,b]$ of the sample space) in N replications of the experiment tends to $f(x)$ (or to the integral of the PDF from a to b) as N tends to infinity.

Conditional Probability and Independence

Many compound events can be defined from the simple outcomes of an experiment. In the roll-of-the-die experiment, the event that an odd number occurs or the event that either a 1 or a 5 occurs are two examples. In some cases knowing that one event has occurred can impact the likelihood of another event occurring. For example, if the faces of the die are equally likely (all have a probability of 1 of 6), then the probability of a 1 or 5 occurring given that an odd number has occurred is 2 of 3, while the probability of a 1 or 5 occurring with no other event information is 1 of 3. The random variable X takes the value 1 if the die falls on face 1 or 5, and 0 otherwise, and the random variable Y takes the value 1 if the die falls on an odd-numbered face are said to be dependent. Two random variables X and Y are said to be independent if $P(X = x|Y = y) = P(X = x)$. The notation $P(X = x|Y = y)$ is read “the probability that $X = x$ given (or conditional on) $Y = y$.” It is the probability that the event $X = x$ occurs calculated in the outcome space defined by the event $Y = y$. Formally, $P(X = x|Y = y) = P(X = x \text{ and } Y = y)/P(Y = y)$. Also, two random variables are independent if the probability of the joint event $X = x$ and $Y = y$ is equal to the product of the probabilities of the two events, that is, $P(X = x \text{ and } Y = y) = P(X = x)P(Y = y)$. Independence and conditional probabilities play a major role in statistical thinking. For example, suppose treatment assignment and degree of improvement on a five-level clinical global scale (CGI) is reported in a table with five rows (CGI) and two columns (treatment or placebo). A chi-square statistic is used to analyze such contingency tables for testing the independence of two random variables that define the rows and columns. If the statistic is significant, the data suggest that the variables are dependent, and the distribution of CGI outcomes conditioned on a value of treatment assignment differs depending on the value of the conditioning variable. If treatment and placebo improvement rates differ, then one would expect a chi-square test to be significant because the distribution of CGI conditional on receiving the treatment is not the same as the distribution conditional on receiving a placebo.

Parametric Forms

In parametric analyses, the *form* of the PDF is assumed to be known with the exception of the value of one or more parameters, which, once specified, completely determines the distribution. The most commonly assumed parametric form is the so-called Gaussian or normal distribution. The shape of the normal PDF is the familiar bell-shaped curve, whose peak (mode), mean, and median occur at the same value. In fact, the curve merely translates to the right or left but retains the same form as the mean is respectively increased or decreased. Distributions with this property are called *translation parameter families,* and they have the mathematical form $f(x - \varphi)$, where φ is the mean of the random variable X. Greek letters, such as φ, are often used to represent parameters of the PDF to distinguish them from random variables. The logistic, beta, exponential, F, and t, for continuous random variables and the binomial, multinomial, and Poisson for discrete random variables are PDFs that frequently appear in the scientific literature.

Mean, Median, and Variance

A variety of measures that help characterize the nature of a random variable have been defined. Among the most important are the mean, median, and variance. The *mean* is the average of all possible outcomes, weighted by the probability of the outcome. The mean is thought of as a measure of the central tendency of the random variable. It is also called the *expected value*, and if X is the random variable, then it is usually denoted by $E(X)$. The value m is the median if the probability that the random variable X is less than m equals the probability that X is greater than m. The *variance* is the average of the square of the difference between each outcome x and the mean, weighted by the probability of the outcome. The variance, usually denoted by σ^2, and its square root, σ, the standard deviation, are thought of as measures of the spread of the observations about the mean.

Multivariate Random Variables

Most serious investigations of scientific phenomena cannot be described by the outcome of a single random variable. A multivariate probability distribution describes the chance of various outcomes of an experiment in which k events are observed on each "unit" in a sample. Typically in trials in mental health, a unit is a patient, and observations are made on one measure collected over time, many measures collected at one point in time, or many measures collected at multiple times. Two random variables, X_1 and X_2, may be independent or dependent. As discussed above, they are independent if and only if their joint (simultaneous) probability function, $f(x_1, x_2)$, is always equal to $f_1(x_1)$ times $f_2(x_2)$. The PDFs $f_1(x_1)$ and $f_2(x_2)$ are called the *marginal distributions* of X_1 and X_2.

Covariance and Correlation

One important measure of the relationship between dependent pairs of random variables X_1 and X_2 is the covariance, the average of the product of the difference between each outcome x_1 and its mean and the difference between each outcome x_2 and its mean, weighted by the probability of the joint outcome x_1, x_2. Closely related is the correlation, usually denoted by ρ, which is defined to be the covariance divided by the product of the standard deviation of X_1 and the standard deviation of X_2. The distribution most widely used in multivariate applications is, by far, the multivariate normal. If the mean and variance of each of the random variables and the covariance between all pairs of random variables are known, then the multivariate normal distribution is completely specified.

USING DATA TO ESTIMATE PARAMETERS

The scientific question under consideration must be represented by a statistical model, which at least approximately characterizes the set of outcomes that can be observed after the data collection is complete. If the model, represented in parametric form as the PDF f(x, φ), is fully known, there is little left to do. Neither an experiment nor statistical inference is needed. The probability distribution is the answer to the question: If the experiment is performed, what can be expected with what probability? But the true value of the distribution is rarely known, and the reason for the experiment is to collect data so that something can be said about the nature of the PDF and the value of the parameters that specify it. This section discusses the problem of parameter estimation. It begins with a description of the method of maximum likelihood. Some of the properties that are used to appraise the merits of an estimator are described. Confidence interval (CI) estimators and their interpretation are introduced.

Point Estimators

In many application areas, the general form of the parametric distribution that describes the collected data is well established. After an experiment is performed, the first question an investigator should attempt to answer is what values of the unknown parameters within the assumed PDF form best represent the data. This is the setting of the theory of statistical estimation, which has a rich and long history. Of course, the principal goal is to come as close to the true value of the parameter as possible. Estimation theory is concerned with the problem of how to obtain an estimator and appraise its worth, not in an individual case but over all possible outcomes, weighted by the probability of the outcome. Perhaps the premier approach, introduced by Sir Ronald Fisher, is the maximum likelihood estimation (MLE). The idea is both intuitive and simple. Suppose that the parameter φ is unknown and f(x, φ) is the probability of observing the event x. The likelihood is just f(x^*, φ), where x^* is the value of the observed outcome. Here x^* is fixed, and f is thought of as a function that depends only on φ. For any given φ, the likelihood is a measure of how "likely" the observation x^* is had the outcome been selected randomly from the probability distribution f with parameter φ. If the observed random variables are independent, then the likelihood is the product of the likelihoods of each observation. It is a measure of the probability of the joint occurrence of x_1^*, x_2^*, …, and the maximum likelihood theory posits that φ should be chosen so that the probability of the event that was actually observed is as large as possible. Any other choice of parameters would make the observed data set less likely to have been observed. For example, if a coin is tossed 20 times, landing heads 10 of the times, setting the probability of a head, P, equal to 10 of 20, or .5, is perfectly sensible. In fact, under the assumption that the distribution of the random variable (the number of heads) is binomial, it makes the chance of 10 heads in 20 tosses maximal. Setting it equal to a lower or higher number makes the estimator less consonant with the data. In a great many cases, the properties of the MLE are very desirable.

Properties of Estimators

Since an estimator is itself the result of a random experiment, it is a random variable, and so it has a mean or expected value. The theoretical calculation of its mean involves the use of the density f(x, φ), where the true value of φ is unknown. We refer to the estimator as *unbiased* if, for each value of the parameter φ, the mean of the estimator is φ. Such estimators exhibit a kind of impartiality that is usually desirable. Another property of an estimator concerns its behavior as the sample size of the experiment increases. Imagine a sequence of estimators in which the ith estimator is based on a sample of size i. For example, the ith estimator in the sequence could be the sample mean based on a sample of size i. An estimator is said to be *consistent* if for any true value φ the sequence converges to φ. Another property of an estimator concerns its precision, as measured by its variance. An estimator is said to be *efficient* if it is unbiased and its variance is as small as it can possibly be compared to any other unbiased estimator. In some situations, a lower bound for the variance of an estimator can be determined. In this circumstance, the *relative efficiency* of an estimator can be determined by comparing its variance to the theoretical minimum variance. Consistency suggests that as the sample size increases, the variance decreases, and the estimator approaches φ.

Confidence Interval Estimation

Even if an estimator has all of the most desirable properties, it is not likely that it will be exactly right. To leave a little wiggle room, an interval estimate, in addition to a point estimate, is desirable. These are termed CI estimators. The amount of confidence placed on the estimator, in the sense that the parameter being estimated lies within the interval, is called the *confidence level* or *confidence coefficient*. The usual form of a CI is $P[a \le \varphi \le b] = c$. If $c = .95$, this is read: $[a,b]$ is a 95% CI for the parameter φ or; $[a,b]$ is a CI for φ with confidence coefficient .95. Typically for a fixed sample size, as the confidence coefficient increases, so too does the length of the interval. An interval from minus infinity to plus infinity with confidence coefficient 1 always covers the unknown parameter, but it is completely uninformative.

Interpretation of a Confidence Interval

It is important to understand how to interpret a CI. From a frequentist point of view, the probability of an event is characterized by the frequency with which the event occurs in infinitely many replications of the experiment. The form of the interval before the experiment is conducted is usually given in terms of some not yet observed random variable. For a normal random variable with mean φ and variance one, the probability statement $P[\bar{X} - 1.96/\sqrt{N} \le \varphi \le \bar{X} + 1.96/\sqrt{N}] = 0.95$, where $\bar{X}$ is the arithmetic mean of N observations, has a clear and unambiguous meaning. Suppose that a random sample of $N = 100$ observations is repeatedly drawn from a population governed by a normal distribution with mean φ and variance 1. As the number of repeated draws becomes very large, regardless of the true value of φ, the proportion of times that the interval $\bar{X} - 1.96/\sqrt{N} \le \varphi \le \bar{X} + 1.96/\sqrt{N} = \bar{X} - 0.196 \le \varphi \le \bar{X} + .196$, $\bar{X}$ covers φ approaches .95. Once data are collected, however, the game has changed. The statement $P[0.304 \le \varphi \le 0.696]$ can only take the value 1 or 0, depending on whether or not the true value of φ falls in the interval. So, from a frequentist point of view, it is incorrect to think of the confidence coefficient of a CI estimate as the probability that the observed interval includes the true value of the parameter. Rather, it is a statement about the joint probability that the random variable that defines the lower limit falls below φ and the random variable that defines the upper limit of the interval falls above φ (before data are collected) for any true value of φ.

USING DATA TO TEST HYPOTHESES

A statistical hypothesis is a statement about the possible values of the parameters of a probability distribution. In this section, test statistics are introduced, and the potential errors that may arise in testing a statistical hypothesis are discussed. The roles of power and the ubiquitous *P* value in hypotheses testing are presented.

Hypothesis Testing

Sometimes interest is focused on answering a scientific question about a random variable with a (qualified) yes or no. Is drug 1 more effective than drug 2? In such cases, the goal often is to determine whether the mean of one distribution is larger than the mean of another. Many scientific questions can be framed in statistical terms as a hypothesis test about the parameters of a probability distribution. Suppose that a clinical trial is designed to test the null hypothesis that two treatments have the same mean effect. Formally, the treatments have true mean effects, denoted respectively by parameters φ_1 and φ_2, and our interest lies in testing whether the difference between the parameters of the two treatments $\varphi = \varphi_1 - \varphi_2$ is 0. The null hypothesis then is $Ho{:}\varphi = 0$. Many alternative hypotheses are possible. The two most common in this setting are the two-sided alternative $H_1{:}\varphi \neq 0$ and the one-sided alternative $H_1{:}\varphi > 0$ (or $H_1{:}\varphi < 0$). A test statistic must be chosen to test the null hypothesis against the alternative. Notably, different alternative hypotheses often lead to different rejection regions for the same test statistic. If the data from both treatments are assumed to follow a normal distribution, and both have the same albeit unknown variance, then the test statistic usually used is a student's *t* statistic, which has the form

$$t = (\overline{x}_1 - \overline{x}_2)\Big/\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}$$

Here, $\bar{x}_1$ and s_1, and $\bar{x}_2$ and s_2 are estimates of the mean and standard deviation based on samples of size n_1 and n_2 from the two respective populations. The t distribution depends on the expected value of $\bar{x}_1 - \bar{x}_2$, which is $= \varphi_1 - \varphi_2$, the variance of the random variable, and sample sizes, n_1 and n_2.

Type I and Type II Errors

The decision as to whether to accept or reject the null hypothesis is determined by the value of the test statistic, which, of course, is a random variable whose value is unknown before the data are analyzed. If the value of the statistic falls in a prespecified *rejection* or *critical* region *R*, the null hypothesis is rejected. Even if the null hypothesis is true, there is still a chance that the statistic will lie in *R*, in which case a type I error has occurred. That is, a true null hypothesis has been erroneously rejected. Alternatively, the test statistic may not fall in *R*, although H_o is not true, in which case a type II error has occurred. That is, a false hypothesis has not been rejected. Both kinds of errors must be considered in choosing *R*.

Usually, the choice is made so as to ensure that the probability of a type I error, usually denoted by the Greek letter α, is small. In most clinical trials, *R* is chosen so that α is .05, although in some applications choosing a type I error rate of .10 may be reasonable. This value is called the *level* of the test. For the comparison of two means, the calculation of this probability is performed under the assumption that $\varphi = 0$, a *point* or *simple* null hypothesis. If the alternative hypothesis is $H_1{:}\varphi \neq 0$, and the sample sizes are large, then the hypothesis is rejected if the *t* statistic is either less than –.168 or greater than 1.68. These are the *large sample critical values* of a *t* distribution with $n_1 + n_2 - 2$ degrees of freedom with α set equal to .05. This is the so-called two-tailed test. If the alternative hypothesis is $H_1{:}\varphi > 0$, the null hypothesis is rejected if the *t* statistic is greater than 1.96.

If there are only two parameter values under study, that is, two simple hypotheses, which one should be labeled the null and which the alternative? The null hypothesis should be chosen to be the one whose false rejection would be considered to be the more serious error. This is because the testing paradigm that selects α, the level of the test, controls the probability of this error.

Power of a Test

The probability of a type II error, or rather one minus this probability, is called the *power* of the test. Since the alternative hypothesis contains many values of φ, it is called a *composite* hypothesis—power is a function of the possible values of φ in H_1. In our example, power is an increasing function of φ and the sample size and a decreasing function of σ^2. During the design phase of a study, the sample size is chosen so that the power to reject a false null is relatively large, perhaps .8 or greater, for a value of φ that is sufficiently large to be clinically meaningful. The calculation is often performed under an assumed value of σ^2 that is based on data from other similar clinical trials. Suppose that the estimated value of φ turns out to be a number that is smaller than the clinically meaningful value chosen when the power calculation was performed and that the test statistic falls in the critical region. There is no difference in the statistical interpretation of the results of the trial. The hypothesis is still rejected at the designated level of the test.

P Values

Even a casual reader of the psychiatric literature will encounter a study in which *P* values are reported. Unfortunately, in some articles, only *P* values appear without estimates of the parameters themselves or the variance of the estimators. All too often, both the author and the reader misinterpret the *P* values. Does a very small *P* value mean that one of the treatments is very much better than the other?

A good place to start is with an explanation of the meaning of a *P* value. Before the analysis of data commences, the value of the test statistic is, of course, random, and in the example, the comparison of two treatments, it follows a *t* distribution. Suppose that the null hypothesis being tested is true, so the expected value of $\bar{x}_1 - \bar{x}_2 = 0$. In this case, the distribution of the statistic is completely specified. It follows a *t* distribution with $n_1 + n_2 - 2$ degrees of freedom. So, for every possible value of the test statistic, the chance of obtaining a value more extreme can be computed or found in a table. If t^* is the value of the test statistic observed in the trial, then the corresponding probability of observing a more extreme value is defined to be the *P* value. Alternatively, the *P* value may be regarded as the smallest level (had it been chosen in advance) for which the hypothesis would be rejected with the observed data. But a small *P* value and a true null hypothesis are inconsistent, for were the trial repeated over and over again, obtaining the observed value of the test statistic or a value more extreme would be very rare. This compellingly argues against the null hypothesis and suggests that it should be rejected. Scientific tradition or perhaps convention usually defines rare as an occurrence whose frequency is less than or equal to 1 time in 20. Note well that the fact that the null is rejected does not mean that the magnitude of the difference has any clinical or scientific relevance. The sample size could be so large that even small trivial differences achieve statistical but not practical significance. Also, the inference that a large *P* value implies that the means of the two treatments are equal, that is, proving the null cannot be made. A calculation of the power of the test would help to rule out the possibility that the sample size was not adequate to detect a meaningful difference. More helpful still would be a CI for the parameter whose upper limit falls below any values that would be scientifically or clinically meaningful. Finally, it is necessary to emphasize that in the frequentist tradition of statistical inference, the *P* value cannot be interpreted as the probability that the null hypothesis is true. The hypothesis is not a random event, so it is either true or false. In a subsequent section, the Bayesian approach will be introduced. In this framework, a method for forming the probability or perhaps the degree of belief in the truth of a null hypothesis modified by the collected data will be described.

Testing Multiple Hypotheses: The Family Wise Error Rate (FWER)

In the preceding section, testing a single hypothesis was considered. However, it is rare that there is only one outcome variable, one dose of a drug, or one homogeneous population that is of interest. As the costs of even simple clinical trials increase, it is prudent to consider simultaneous investigation of a variety of issues because gathering additional information may represent marginal additional expenditures. The result of such a strategy is many more hypotheses tests to answer the various questions that may be asked of the data. The collection of statistical hypotheses, each derived from some comparison of interest that relates to a common aspect of the research question, is referred to as a *family of hypotheses*. For example, three doses of a drug and a placebo may be simultaneously studied in a clinical trial. The doses are each to be compared to a placebo. The three contrasts, high dose versus placebo, middle dose versus placebo, and low dose versus placebo, are a family of hypotheses. *A priori,* it is possible that all of the null hypotheses in the family are true. Testing each of these at a specified level α ensures that the probability of a type I error of each contrast is α. But, it is prudent to ask, what is the probability that one or more of the tests erroneously rejects the corresponding null hypothesis? The probability of erroneously rejecting one or more of the hypotheses in the family is called the *familywise error rate*. Clearly, in general, this probability is much higher than α. Under the null hypothesis, the probability of not making a type I error when testing a single hypothesis at a .05 level is .95. Suppose that a family is comprised of m individual hypotheses. If the test statistics are independent, the probability that none of the hypotheses are erroneously rejected is $.95^m$. Therefore, the probability of the complementary set, that one or more of the m hypotheses is erroneously rejected is $1 - .95^m$. For $m = 3$, it is .14 and for $m = 5$, it is .23. The FWER approaches 1 as m increases.

In many research settings, it is appropriate to require that the statistical procedures utilized should not result in a large FWER. For example, if multiple doses of a putative drug are studied and the drug is ineffective, it would be unreasonable to allow the chance to be high so that one of the doses is found to be statistically different from placebo if the null hypothesis is true. In this section, statistical tests that control the FWER multiple hypotheses tested are discussed. Several procedures for controlling the size of the FWER are presented and their advantages and disadvantages are discussed.

The most widely known approach to controlling the FWER is the Bonferroni method, which is based on a probabilistic inequality. In fact, the inequality is known as *Boole's inequality* and as often happens, the credit for its utilization in simultaneous statistical inference may have been misplaced. If there are m hypotheses in the family to be tested and the type I error level of each test is set to α/m, then the probability of an FWER $\leq \alpha$. That is, each test is performed at a level that is much smaller, α/m, than α, which would be used if there were only one test. The Bonferroni procedure is conservative in that, while it controls the familywise error rate, it renders the chance of rejecting any one of the individual hypotheses considerably lower. As a consequence, the user of this approach pays a heavy price in terms of loss of power. For example, if the family has five hypotheses, then, in order to achieve a FWER of .05, the individual hypotheses must be tested at the $\alpha = .01$ level. If a t test is used for each of the individual hypotheses, then the value of the t statistic calculated after the experiment is complete must be larger than 2.457 in order to reject the corresponding null. If only a single hypothesis were being tested, then the t statistic would have to be larger than 1.697. This makes the task of rejecting any of the individual hypotheses considerably more difficult. On the other hand, the Bonferroni method can be used to control the FWER in any setting. It is easy to use and does not depend on the distribution of the test statistic. Several improvements to this method have been suggested. Sidak modified the Bonferroni approach providing only a slight improvement in power. If the desired FWER is desired to be α, then instead of using α/K, the Sidak cut point is defined to be $\alpha^* = 1 - (1 - \alpha)^m$, where m is the number of hypotheses tested.

In some studies, for example, one comparing K treatments, the investigator is interested in a contrast of each treatment with every other treatment. If say $K = 3$, and the τ_i is the parameter characterizing treatment i, then the family consists of three pairwise comparisons $(\tau_i - \tau_j)$. The first step in analyzing pairwise comparisons is often an analysis of variance on the K treatments. One of the first tests to control the FWER, the least significant difference (LSD) procedure was developed by Sir Ronald Fisher. He argued that if the analysis of variance rejected the null that all three treatments have equal means (the omnibus null hypothesis), then to test the pairwise contrasts, t tests should be computed between each pair. The estimated variance used in the denominator of the t statistic is based on all the data, not just on the data for the two treatments being compared. If there are 30 subjects per group, then a two-tailed t statistic rejects the null for each contrast if it exceeds 2.042. If the analysis of variance is not significant, then neither the omnibus null hypothesis nor any other null hypothesis about differences between means can be rejected. This procedure is valid in that the FWER is controlled for $K = 3$ but it is not valid for any $K >$

3. Its use for such values does not result in tests whose FWER is protected at the α level.

This approach utilizes a staged approach to testing a family of hypotheses. The omnibus test, in the above case an ANOVA, is performed first. Such tests have been called *gatekeeper* tests because they limit the overall FWER. Only after the omnibus test rejects the global null does further testing take place. These tests can be less demanding in terms of power than Bonferroni-like tests without affecting the FWER. The Newmann-Keuls procedure is another well-known example of such tests.

A variant of the LSD procedure is Tukey test for pairwise comparisons. It utilizes a *t*-like statistic called the *studentized range*. Most statistical software packages that compute ANOVAs include routines to compute this test. Tukey test compares each of the K(K − 1)/2 studentized *t* statistics with a single-tabled critical value. If the sample sizes of treatments are the same and each of the pairwise comparisons is to be tested, then many believe that Tukey method is the method of choice. It exactly achieves the desired FWER and has reasonable power. The theory for this test was developed under the assumption that the sample sizes for each treatment are equal. Various corrections have been proposed to handle the unequal sample size case. For example, the Tukey–Kramer test replaces the common sample size in the formula with the harmonic mean of the respective sample sizes, that is, $(1/n_i + 1/n_j)/2$. Though this modification is widely used, the FWER fails to attain its proscribed level in most cases.

Although a clinical trial may involve K treatments, not all pairwise comparisons may be of interest. For example, K-1 new treatments may be in a trial together with one standard treatment. A new medication for an illness may only be worth further study if it is superior to the standard medication, frequently called the control. Here the comparisons of primary interest are each new treatment against the control. Thus, there are only K-1 comparisons to consider. Dunnett derived a test statistic for this problem that is similar to a *t* statistic. However, in this test, the estimate of variance used in the formula is derived from the data from all of the K treatments. The critical value is based on K and the *degrees of freedom*, which is the total number of subjects on all medications minus K. For a given FWER α the critical value may be obtained from published tables. Dunnett test achieves the exact FWER.

The procedures discussed above for multiple comparisons are all specified in advance, but the order in which testing is performed is irrelevant. *Adaptive* or *sequential procedures* modify the process of testing depending on the outcome of earlier tests. They can provide an increase in power while still controlling the FWER. The Holm procedure for testing a family of m hypotheses begins by testing each hypothesis individually using a statistic such as a student's t. Each test produces a P value without multiplicity adjustment, so the experiment yields $p_1, p_2, \ldots, p_m$. These values are then ordered from the smallest to the largest, $p(1) \leq p(2) \leq \ldots. \leq p(m)$. The notation $p(i)$ refers to the ith smallest P value. Relabel the m hypotheses so that H(i) is the hypothesis associated with $p(i)$. If $p(1) > \alpha/m$, H(1) is not rejected, the process terminates and none of the m null hypotheses are rejected. If $p(1) \leq \alpha/m$, H(1) is rejected and the process proceeds to examine $p(2)$. If $p(2) \leq \alpha/(m - 1)$, H(2) is rejected and the process proceeds to examine $p(3)$. Otherwise testing is stopped and H(2), H(3), … H(K) are not rejected. The procedure continues in this manner until a hypothesis is not rejected or there are no further hypotheses to tests. The Holm procedure is more powerful than the Bonferroni test, which requires that each $p(\mathrm{i}) \leq \alpha/m$ as opposed to $p(\mathrm{i}) < \alpha/(m - i + 1)$. The Holm procedure is called a *step-down procedure* because the cut points are in descending order. Note that the p_i are put in ascending order, which sometimes results in confusion as to what the test actually is.

A dual of this step-down testing procedure is the *step-up procedure*, introduced by Hochberg. Here the quantities $p_1, p_2, \ldots, p_\mathrm{m}$ are reordered in descending order $p[1] \geq p[2] \geq \ldots. \geq p[m]$ where $p[i]$ is the ith largest among the $p_1, p_2, \ldots, p_\mathrm{K}$. The hypotheses are then relabeled so that H[i] is the hypotheses associated with $p[i]$. If $p[1] \leq \alpha$, H[1] is rejected as are all of the remaining hypotheses. If *p*[1] > α then H[1] is not rejected and *p*[2] is examined albeit against a modified threshold. If *p*[2] meets the condition, H[2] and the remaining hypotheses are rejected. Otherwise p[3] is examined. In brief the step-up procedure accepts hypotheses in order and at the first nonacceptance rejects all remaining hypotheses.

A *closed testing procedure* may be used to control the FWER on a "closed" family, and the method has some remarkably desirable properties. The procedure sequentially tests members of the family of hypotheses, yet each test is performed at size α. The family of hypotheses is said to be closed under intersection if the family satisfies the condition that if *H* and *G* are any two hypotheses in the family, the hypotheses represented by *H and G* are also members of the family. The sequential nature of the closed testing procedure requires that prior to rejecting any hypotheses, *H*, one must reject all hypotheses that include *H*. For example, suppose the family contains three hypotheses, *G*, *H*, and *J*. Then closure under intersection requires that it must also contain *G and H*, *G and J*, *H and J*, as well as *G and H and J*. To test *H* at level α, one must first test *G* and *H* and *J*, then test *G* and *H* and test *H* and *J*, and finally test *H*. Each of these tests is carried out at level α, and if any test does not reject, then the process ends. The FWER of the closed testing procedure is α.

This procedure has the very desirable property that the first hypothesis is tested at .05 and the very undesirable property that if any test fails along the way, the process stops. It might very well be that one or more of the hypotheses that are not reached would have been found significant had an alternative procedure for protecting the FWER been used. However, once the choice is made, hopefully before the data are examined, there is no going back. Further examination of *P* values is of course legitimate and desirable, but they no longer represent probabilities of a type I error under the null hypothesis.

Comparing a combination medication to each of its component medications is another example of a testing procedure where each test is performed at the α level and yet the FWER is α. Let φ_i denote the mean difference in efficacy between the combination and medication *i*. Federal regulations require that prior to licensing a combination, one must show that each component medication contributes to the claimed effects. One translation of this requirement is that φ_i is positive for every component medication. This leads to the null hypotheses that for at least one component $\varphi_i \leq 0$. If the outcome variable follows a normal distribution and φ_i is the test statistic for $\varphi_i \leq 0$, then the test statistic for the null hypotheses is min $(\varphi_1, \varphi_2, \ldots, \varphi_K)$. Each φ_i is tested at the same α level. This procedure is referred to as the *min test*. It is a simple example of what is known as the union–intersection principle.

Each of these approaches to controlling the FWER has positive and negative properties. Especially if the test statistics are not independent, the Bonferroni method becomes increasingly conservative as the number of hypotheses increases. The sequential procedures are usually more powerful than the other methods described above. However, when the number of false hypotheses in the family is large, they can be problematic. Tests based on the union–intersection relationship also tend to be quite conservative, and they are dependent on the existence of a satisfactory omnibus statistic.

False Discovery Rate

The shortcomings of the FWER methods are never more apparent than when the number of statements in the family of hypotheses is very large. Imaging data presents a prime example. The number of potential statements is enormous, reaching even into the tens of thousands. Consider, for example, the question of whether a given voxel has been activated by a particular stimulus, or whether in a microarray analysis particular genes are differentially expressed. The statistics related to a pair of adjacent voxels will undoubtedly be statistically dependent, and the compound null hypothesis may be partially or even completely false. Under such circumstances, the use of the methods used to control the FWER for simultaneous testing may be useless. Some have instead conceptualized the problem as one of separating the important effects in the image from those that are small or unimportant. The false discovery rate (FDR) is a relatively new approach to the problem of multiplicity. The FDR controls the expected *proportion* of false positives among the declared rejected hypotheses. Just as in FWER methods, each voxel is tested resulting in a *P* value. On the basis of the distribution of the observed *P* values, a threshold is determined. The hypothesis corresponding to those *P* values falling below the threshold is rejected. However, the interpretation of the *P* values is quite different from the approach described above. If 100 genes with a maximum FDR of .20 are declared by the procedure to be differentially expressed, then the expected value of the maximum number of false positives is 20. There is no comparable interpretation that attaches to *P* values. There are four major factors that affect the characteristics of a study utilizing an FDR criteria: (1) the proportion of null hypotheses that are false, (2) the distribution of the variables being assessed, (3) the measurement variability, and (4) the sample size. The investigator has limited ability to manipulate any of these except for the size of the study. The FDR approach provides much weaker control of the type I errors in the test procedure than do the traditional methods described above. This is because the FDR criteria for false positive outcomes (the expected *proportion* of false positives is less than α) are much weaker than the FWER criteria (the probability of one or more false rejections is less than α). Thus, FDR methods are said to have weak control of the type I error.

THE BAYESIAN APPROACH

The formal setting for incorporating prior beliefs into a statistical analysis in which the data modify such beliefs is the essence of the method presented below.

Bayes Theorem

One of the most important results that emanates from elementary probability theory is Bayes theorem, which states

$$P(\mathrm{A}|\mathrm{B}) = \frac{P(\mathrm{B}|\mathrm{A})P(\mathrm{A})}{P(\mathrm{B})}$$

Bayesian inference played a major role in statistical thinking until the early part of the 20th century. Although the hypothesis-testing ideas of Jersey Neyman, Karl Pearson, and Sir Ronald Fisher played a dominant role in the rest of the century, in the past 25 years the tide has begun to turn. The methodology and intuitive logic of the Bayesian approach, made more feasible by high-speed computers, is now pervasive in the literature of modern science and statistics.

Bayesian Inference

Bayes theorem is the basis on which Bayesian inference is built. Suppose that φ is a parameter and that φ = 0 represents the event that the null hypothesis is true. Then according to Bayes theorem,

$$P(\varphi|\mathrm{data}) = \frac{P(\mathrm{data}|\varphi)P(\varphi)}{P(\mathrm{data})}.$$

The parameter φ may be thought of as a representation of the scientific theory under investigation. The left-hand side of the equation is a quantification of the probability, or perhaps degree of belief, of the truth of the proposition that φ represents the true state of nature, given the observed data. In this setting, the unknown parameters are viewed as random variables and as such they follow a probabilistic law. Remarkably, if the right-hand side can be evaluated, a numerical value for the probability can be determined for this quantity, which arguably is the main issue once data collection is complete. It reflects the current belief, given the data, about the veracity of any value of φ and it is called the *posterior* distribution. The first term on the right is just the likelihood of the observed data, evaluated at the parameter value φ. It is the next term that has made Bayesian inference controversial. What is the value of $P(\varphi)$? This quantity is a function of all of the possible values of the unknown parameter φ, and it is called the *prior probability distribution*, or just the *prior* for short. A prior distribution that has the same functional form as the posterior distributions is called a *conjugate* prior. This is a particularly desirable situation, for it permits efficient sequential updating of the posterior distribution as more data are collected. The posterior distribution at one stage is used as the prior in the next.

Note well that the result of applying the Bayesian method is an entire posterior distribution and not a single estimate of the unknown parameter. The posterior summarizes all of the information, past and present, about the unknown parameter value. In the Bayesian framework, issues such as estimation and hypothesis testing are all based on the posterior distribution. For example, sensible estimators of a parameter are the mean or median of the posterior distribution. For hypothesis testing the posterior distribution can be used to calculate the probabilities that the null and the alternative hypotheses are true. One possible rule is to decide to accept the null as true if the ratio of the posterior probability of the null divided by the posterior probability of the alternative exceeds some constant and reject the null otherwise. The interpretation of a *P* value in this context is more natural than it is in the frequentist paradigm. The value of *P* is in fact the probability that the null hypothesis has been erroneously rejected. Contrast this with the frequentist interpretation that *P* is the chance of obtaining a data set that is more extreme.

The controversy about the use of Bayesian inference hinges on the problem of objectively choosing a prior. In many if not most cases, knowledge gleaned from previous experiments and perhaps scientific theory can guide the mathematical specification of $P(\varphi)$. However, in situations in which little is known or there is controversy about prior experience or relevant theory, the choice of the prior is subjective. There are two schools of thought about choosing the prior. In one approach the prior reflects the individuals' real-world experience and insights. An alternative approach is mechanistic or objective. The prior is chosen to satisfy some property; for example, it is noninformative or it is the conjugate distribution.

What price is paid for introducing subjectivity into the scientific process? Supporters of the Bayesian approach argue that Bayes theorem mathematically demonstrates the inevitability of a subjective component to scientific inquiry. Scientists are the first to admit that insight, intuition, judgment, and beliefs are part of the process that drives their practice. Regulatory bodies are less convinced, but even in such scientifically driven agencies such as the U.S. Food and Drug Administration (FDA), Bayesian approaches frequently appear. A full discussion of how the a priori distribution can be specified and the dependence of the final a posteriori distribution upon this choice is somewhat technical. Needless to say, there are a wide array of formal a priori distributions, including a noninformative prior, that is, one in which values of the parameter are equally likely, that can be used. A commonly used approach is to specify a range of priors and examine the degree to which conclusions are sensitive to the choice. The more robust the finding under different priors, the more believable they are.

RANDOMIZED CLINICAL TRIALS

There are many kinds of research projects in mental health that require the use of statistical methods to appraise the results. Here the discussion is focused on randomized clinical trials because they are important and ubiquitous, and many of the issues apply in other research contexts. The methods discussed are neither exhaustive in the range of topics covered nor are they complete in the detail that is required to appreciate the nuances fully. The goal of many mental health studies is to conclude “causality,” that is, some observed effect is the result of an intervention. To begin, this is a model that leads to conditions under which causality may validly be concluded. This may be accomplished by randomization or by using matched subjects. In the situation where matching is practically difficult, an alternate approach, the propensity score is introduced. The section concludes by introducing randomization tests that are valid regardless of the underlying distribution of the random variable of interest.

Causality

The principal reason for carrying out clinical research is to demonstrate the causal effect of the treatments being studied. Donald B. Rubin described an approach by which causality can be demonstrated in a clinical trial. Suppose that a putative antidepressant is given to a well-diagnosed patient suffering from the illness. If the patient does poorly, assuming the agent does no harm, no evidence is adduced about its effectiveness. Suppose the patient does well and there is a considerable reduction in symptoms. How can it be concluded that the treatment was the causal agent? If the clock could be turned back and the same patient with the same symptoms did not benefit from placebo treatment, it would be reasonable to conclude that administration of the test agent caused clinical improvement in this patient. Each patient has two hypothetical outcomes, O_T and O_P, which would result from being treated with T or P, respectively. If this hypothetical thought experiment were repeated a large number of times, then the frequentist would conclude causality if the average effect of an individual receiving the treatment is larger than the average effect produced by placebo in the same individual. In statistical terms, it would be written $E(O_T - O_P) > 0$, and it would be recognized that the concept is the same whether the hypothetical experiment is repeated over and over with the same patient each time or with different patients. But the generalizability of the conclusion is not the same in the two cases, and from a statistical perspective the interest is in population causality rather than individual causality. Of course, the clock cannot be turned back, so what other possibilities are there? If each of the patients has an identical twin with the same genetic makeup and identical clinical symptom profiles, then one of each pair could be given the test treatment and the other given placebo. If the former improved and the latter did not, a causal relationship has been demonstrated. That is, it has been demonstrated that $E(O_T) - E(O_P) > 0$. Unfortunately, in the real world, each subject has only one outcome, O. If the treatment assignment is T, then the outcome is

O_T, and if it is P, then the outcome is O_P. One of the two is counterfactual. In this case, $E(O|T) - E(O|P) = E(O_T) - E(O_P) = E(O_T - O_P)$. What is necessary to be able to conclude causality is a mechanism that would enable the conclusion that $E(O_T - O_P) = E(O_T|T) - E(O_P|P) > 0$, where the expectation on the left-hand side indicates that each individual received both treatments and the expectation on the right-hand side indicates that each individual received only one of the treatments. The notation beyond the vertical bar indicates which treatment was assigned to the patient, and the expectation, the computation of the average over the population, is restricted to those receiving the indicated treatment. Suppose that the treatment assignment is a random variable determined by some mechanism that is independent of the outcome, O. For example, suppose a patient is assigned to the test treatment if a fair coin (one whose probability of each of the two outcomes is .5) lands heads and to placebo otherwise. Then the treatment assignment is independent of the outcome random variable, O. But then $E(O|T) - E(O|P) = E(O_T) - E(O_P) = E(O_T - O_P)$. So, the use of a random assignment mechanism enables conclusions of causality.

Note that the coin did not have to be a fair coin for the treatment assignment to be random. The same conclusion on causality would be reached were the probability of assignment to the treatment group equal to, say, .6. This is called a *biased coin random allocation*. The only difference is that the result of such a randomization process would be that more individuals would tend to be assigned to the treatment group (about 60%) than to the control group (about 40%). This fact is important for the application of propensity score methods, which are discussed below.

In fact, the idea extends to situations in which treatments are assigned to subjects based on factors z that are observed. For example, z might be severity at baseline or some other stratification factor. Even *response adaptive designs*, where the probability that the next subject is assigned to the test treatment depends on outcomes observed on patients studied earlier in the trial, can demonstrate causal effects so long as the response to treatment and assignment to treatment are independent, conditional on z.

Matching and Randomization

Suppose that a clinical trial is to be conducted to establish a causal relationship between receipt of a treatment believed to be an active drug and clinical improvement, the effect produced. The treatment is to be allocated to one group of patients and a control treatment, a placebo, is to be allocated to another. As was just seen, the control group can be comprised of one member from each set of twins and the test treatment group the other twin and causal conclusions can be reached. Although such a design can only rarely be realized, matching two groups on all variables that are prognostic indicators of the outcome may be feasible. Subjects can be matched on the basis of characteristics such as age, weight, severity, prior episodes, genetic factors, family factors, and on and on. However, in psychiatric research, it will be a rare study indeed in which the investigator and more importantly the target audience of the research believe that the two groups are truly matched. However, there are some circumstances in which this will be the best approach, and such cases need to be appraised individually. In the idealized twin case, treatment assignment need not be random. But here, since there is no guarantee that paired subjects are truly identical, for causal inference the assignment mechanism within the pair must be random.

Randomization helps to avoid systematic bias, for example, evaluating one treatment in older or more severely ill patients and the other in younger or less severely ill patients. It has no effect on selection bias, which chooses individuals to participate in the study who are not representative of the target population. For example, in most drug comparison studies, the various eligibility requirements, both inclusion and exclusion, as well as the option candidates have of declining to participate in the trial bias the sample. However, this does not compromise the validity of the treatment contrasts so long as treatments are randomly assigned to participants.

The very mechanism of assigning treatments to subjects in the clinical trial provides the probabilistic basis for computing, under the null hypothesis, valid probabilities of the various possible experimental outcomes. But this is exactly what is needed to assess the likelihood that the null hypothesis is true. In particular, it enables calculation of a rejection region corresponding to a chosen type I error, which is the basis of hypothesis testing. Further, because randomization guarantees that outcomes for different subjects are independent, a valid estimate of the experimental error can be obtained. This quantity is required for obtaining valid CI estimates of treatment effects and for parametric testing of a null hypothesis. Also, given a sufficiently large sample size, all of the possible known and unknown confounding effects that might possibly affect outcome are, with high probability, eliminated in the sense that they are averaged out. Finally, the objectivity and repeatability of randomized assignment to treatment must be pointed out. There is no point in conducting a clinical trial whose results will not be creditable. The ability to describe exactly how candidate patients were placed into the various treatment groups makes transparent the process and gives credence to the conclusions reached.

The Likely Responder Method of Analysis

The premise of precision medicine is that there is diversity in patient response to a treatment as a function of baseline characteristics. For mental health disorders, whose presentations are highly variable, individual care would substantially improve if treatment were based on patient-specific characteristics. In an RCT, the opportunity to discover the best treatment practice is often eclipsed by obeisance to the classical hypothesis test of mean difference between treatments in the whole sample. Finding responder subtypes is relegated to secondary analyses, designed to provide input to the design of the next trial. This analytic strategy, on its face, makes no sense if the premise of precision medicine pertains. The Likely Responder approach to the analysis of an RCT reverses the order: first the subset of patients likely to respond to the test treatment is identified. Then a test of treatment differences is performed on patients in this group matched on baseline features. This causal analysis of treatment effect is carried out in a potential outcome framework. The Likely Responder approach was used for the first time in a reanalysis of a gabapentin clinical trial for the treatment of alcohol use disorder by Laska, Siegel, Lin, and their colleagues. While there were no treatment differences in the whole RCT sample, there were in the subset of likely responders.

Randomization Tests

Randomization tests make no assumptions as to the distribution of the random variables and so are considered to be distribution free. The results of the test depend only on the data actually collected. Suppose there are two groups of patients, whose group assignment is determined by a randomization procedure, with one group receiving the test treatment and the other receiving a placebo. After a suitable period of time, an outcome is obtained on each subject. The quantity of interest is the difference between the mean outcomes of the two groups. The first step in a randomization test is to compute the statistic, the difference between means, from the sample. The second step is to rerandomize and recalculate the value of the mean difference for the new treatment assignments. Under the null hypothesis, there is no difference between the groups; so reassigning some patients from one group to the other should not change any probabilistic properties of the distribution of treatment differences. Reassigning treatments to patients by rerandomization (or, for small numbers of subjects by exhausting all possible permutations of possible treatment assignments) and recalculating the mean differences induce a probability distribution of mean differences. The percentile in the randomization-induced probability distribution of the actual mean difference observed in the trial is informative about the plausibility of the null hypothesis. If the observed mean difference lies near the middle of the distribution, the null distribution seems likely to be true. If, on the other hand, the observed mean difference falls into one of the extremes of the randomization distribution, say less than .05 (α) of the values are larger, then the null hypothesis seems unlikely to be true. The mean values of the two treatments are likely to be different. The randomization *P* value is the proportion of rerandomizations in which the value of the statistic is more extreme than the value obtained from the original treatment assignment. Randomization tests produce valid significance levels (probability of a type I error) regardless of the usually unknown underlying probability distribution of the outcome measures.

Rank randomization tests are similar to randomization tests. However, first the observations are converted to ranks. That is, the two groups are merged and put in numerical order. The largest is assigned rank one, the second largest rank two, and so on. Next, the two groups are separated into their original configuration, and a randomization test is computed on the ranks. This is a particularly useful approach when the scale used to measure patient response has some nonlinear properties and when outliers in the data might skew estimates of mean effects. The disadvantage is that some information is lost when the actual observed values are converted to ranks. Although rank randomization tests may be somewhat less powerful than randomization tests based on the original data, the loss in power may be a small price to pay to purge the potential contamination caused by exceptional large or small outcomes.

Propensity Scores

In efforts to understand the properties of a new treatment or intervention, it is often impossible or too expensive to conduct a randomized clinical trial. On the other hand, there may be data available on the new treatment as well as on standard practice that has been collected under naturalistic conditions. In earlier sections, considerable attention was paid to the merits of randomization and the benefits that accrue from its use. Randomization of persons to treatment or control groups allows statements of causality to be made, and systematic differences in characteristics between the groups are not likely to occur if the sample size is sufficiently large.

Is it possible to nevertheless obtain valid estimates of effect size from data on patients who were not randomly assigned to treatment? Many standard statistical methods of analysis are not appropriate because they implicitly (at least for the purpose of causal inference) assume that the groups were formed by random assignment.

Suppose that background characteristics, some known, such as severity of illness and age, and others that may not be known, are markers for the assignment of patients to a new treatment or to a control or usual practice group. This might occur as part of usual care procedures or by unconscious hunches designed to individualize and optimize treatment outcome. If the two groups are compared without regard to the treatment assignment mechanism, the results can be biased particularly if there is an imbalance across groups in variables that influence outcome.

If there are only a few confounding variables and they are known, it may be possible to form a stratum in which the treatment and control group look alike. For example, suppose there is a difference in the proportion of males receiving treatments in the two groups. Then a group containing only males and a group containing only females can be formed. The treatments can be compared within groups and if they are similar the results can be pooled.

If there are two known confounding variables, such as age (young, middle aged, and older adults) and gender, then age/gender groups can be formed yielding six strata in which to make comparisons. However, as the number of confounding variables grows, it becomes increasingly difficult to form the multiple strata that would be required. Sample sizes in each stratum would considerably diminish, resulting in a loss of power to detect differences when they truly exist.

Propensity score methods are used to control for a collection of confounding covariates. The propensity score is a probability of treatment group membership based on patient covariates. An estimate of the propensity score for each individual in the study is usually obtained by first fitting a logistic regression and then substituting his or her covariates into the resulting model. Naturally, persons who are actually in the treatment group will tend to have higher propensity scores than those in the control group. If the range of propensity score values in the two groups overlap, then it is possible to match individuals in one group with those in the other group who have like scores. Rather than one-to-one matching, usually the propensity scores for the combined groups are ordered, and five strata, that is, quintiles, are formed. Within a stratum, all individuals have approximately the same estimated likelihood of being assigned to the treatment group, and the multivariate distribution of the covariates used to estimate the propensity score in the two groups do not differ statistically. Across strata, the likelihood of being assigned to the treatment group differs. Within each stratum, some individuals were assigned to treatment and some to the control, so biased coin randomization has in essence been mimicked. If all subjects have a propensity score of about one-half, then treatment assignment appears to have been determined by a fair coin randomization process. Treatment effects are estimated within propensity score strata, and if the results are similar, they can be combined to obtain an estimate of the overall effect size. As Philip Lavori put it, within each observational study there lives a randomized study that can be found with the help of propensity scores.

More on Causality

When possible, causal relationships are inferred by manipulating the causal agent and determining its effect on the target in an experiment. However, there are many instances in which experiments are not possible and only observational or naturalistic data can be obtained. For example, a researcher studying the development of Posttraumatic Stress Disorder (PTSD) may hypothesize that different trauma types (combat exposure, motor vehicle accident, sexual assault) differentially affects the likelihood of the emergence of PTSD.

Causal Graph Models, which utilize directed acyclic graphs (DAGs) to represent causal relationships between variables or events, has been developed to facilitate causal inference in such situations. A DAG is simply a mathematical model described pictorially with arrows (edges) connecting vertices (variables or events) whose chance of occurrence are given by conditional probability distributions. Typically, arrows point in the same direction from *parent* or *ancestors* nodes (the cause) to *child* or *descendent* nodes (the consequence.) *Paths* refer to a sequence of edges connecting one node to another possibly distant node; *causal paths* are those leading from a causal node to an outcome node. *Colliders* are nodes at which two edges converge. Necessarily, such graphs are acyclic in that there are no paths in the graph that start at one node that eventually loops back to the same node. The goal of this technique is not discovery of an *association*, statistical dependence between variables. The goal is determination of causality. The simultaneous presence of the symptoms of streptococcus and streptococcus bacteria is a dependence relationship (they are not independent) which is substantially different from the causal chain: the presence of symptoms is caused by the presence of the bacteria. A dependence relationship cannot differentiate disease causes symptoms and symptoms cause disease.

A *Bayesian network* is a DAG in which the nodes are events together with their probability distributions that depend only on the probabilities of prior events. In this sense, a probabilistic DAG formally encodes knowledge and beliefs about causal and potentially causal relationships among variables through visual representations. Edges represent conditional dependencies while nodes that are not connected are conditionally independent. A probabilistic DAG has two primary purposes: to represent assumptions explicitly in order to reveal testable causal hypotheses and to enable explicit data driven hypotheses testing of these causal effects. This approach sharply contrasts with traditional hypothesis testing approaches that assume a null relationship which is rejected when data supply sufficient evidence of incompatibility. In Bayesian network theory, potential relationships between nodes are specified in a DAG and data is used to sustain or reject the relationships. Many algorithmic computer programs have been written to discover causal graphs by hypothesizing edges between all nodes and removing those that are incompatible with data.

Missing or Incomplete Data

In the conduct of research in mental health settings, having missing data is inevitable. Such data sets are said to be “incomplete,” and the problem of parameter estimation or hypothesis testing is regarded as an “incomplete-data” problem. Missing data problems occur both in clinical trials and in studies that are survey or field based, and the data can be missing for many reasons. In a clinical trial in which data are collected at multiple time points, subjects may not be available for all interviews. Some may drop out of the trial before it is completed because of adverse events or death, or they may move to another home, hospital, or jail or to the streets, or they may just perceive continuing in the trial to be a nuisance. In surveys, respondents may refuse to answer particular questions because of the sensitive nature of the inquiry, or they just may not know the answer.

There is no one approach to handling all missing data situations, but ignoring holes in the data when performing a statistical analysis can have an enormous effect on the results. The possibility of substantial structural biases that might have led to the data losses can lead to analyses that may even be so fatally flawed as to nullify the results. Conceptually, the complete data set consists of two parts, only one of which is observed. The missing part can only be inferred from the observed part. The steps to take depend on the mechanisms that led to the missing data. This is often referred to as the *missingness* of the data. Roderick Little and Donald Rubin have defined three kinds of missing data mechanisms: Missing completely at random (MCAR), missing at random (MAR), and nonignorable missing.

A very simple probabilistic model can be used to conceptualize data that are MCAR. Suppose that a random variable taking the value 0 or one with respective probability P and $1 - P$ was observed for each observation of the variable Y. Assume further that the value of the observation on Y is independent of the binomial random variable. Such a random variable is obtained by tossing a coin whose probability of landing heads is P. If the coin toss corresponding to a particular observation of Y lands heads, the data are lost. The remaining observations are a random subsample of the original sample and so the data remain a random sample.

An example of MAR can be obtained in a similar fashion. Suppose Z is gender, and a coin is tossed for males with probability P_1 of landing heads, and a second coin is tossed for females with probability P_2 of landing heads. For each observed Y, one or another coin is tossed depending on the gender as captured by Z. If the coin lands head, the data are lost. The remaining data in each subsample is still a random sample.

As an example of nonignorably missing, suppose the observations on Y have been sorted into good and bad outcomes, and two coins are tossed with respective probabilities of heads P_1 and P_2 for the two types of outcomes for each observation. If either coin lands heads, then the corresponding observation is lost. The remaining data no longer arise from the same underlying probability distribution that gave rise to the original sample. If $P_1 = P_2$, then the effect of sorting an outcome no longer matters, and the subsample is a random subsample of the original sample. In this case the data would be MAR.

There are several methods used to handle the situation when data are MCAR or MAR. Certainly, the simplest strategy is to delete from the study those records with missing data on the primary variable of interest. If the sample size is sufficiently large, this may be a viable approach. However, if the amount of information lost diminishes the ability of the study to reach confident conclusions, then this method is not recommended. If the data are multivariate and only some of the variables in a record are missing, it would be rather wasteful to dispose of the entire record. Some analysts retain those parts that have data that are present and use them in marginal analyses not involving the variables with missing data. This approach too can be problematic. For example, suppose a clinical trial is designed to compare an active treatment with placebo. Those individuals who respond to the placebo remain in the trial, while the others drop out. For a self-limiting illness, the placebo responders and the treatment responders are not likely to differ toward the end of the trial. Ignoring the early dropouts and limiting the analysis to those who remain in the trial could lead to the erroneous conclusion that the drug loses its efficacy after a while. Filling in or imputing the missing data with a conservative estimate of its value is the current favored approach. However, this strategy too can lead to erroneous conclusions if there are too many records with missing data. Neither strategy is completely satisfactory nor is there a satisfactory rule of thumb as to how much missing data is too much for imputation. Individual variations among studies require critical appraisal in each particular case as to what is an appropriate analytical approach.

Imputation of missing data can be done in several ways. One simple imputation procedure is called *mean/median substitution*, in which the mean or median value of the observed data is substituted for the missing value. This approach tends to reduce the estimated variance, which thereby provides more comfort to the researcher than may be warranted. Several methods rely on a matching strategy. Records with missing data are matched with records of subjects with similar demographics whose outcomes are present. The data from the matched records are used to impute the missing value. In *hot deck imputation* cases the missing data are matched with similar cases with complete data on the basis of defined background variables, for example, age and gender. A critical issue is how to choose the variables that define “similar.” Matching criteria variables are chosen because they are prognostic indicators of the missing data variables. The value substituted for the missing value is randomly selected from data present in the set of matched cases. *Multiple imputation* uses an imputation method such as hot deck to repeatedly generate estimates for the missing data values. For each replication, the full data set, actual and imputed, is analyzed. The results from these multiple analyses are combined into one overall analysis. This approach gives an idea of the variability of the results among the various possible imputations that could have randomly been selected.

For data collected longitudinally, many researchers have used the last observed value carried forward (LOCF) approach to fill in the missing value. If values are available before and after the missing time point, many interpolate a value. These approaches too tend to reduce the estimated variance, which can lead to a greater chance of reporting an effect when there really is none. Hierarchical linear modeling provides a more satisfactory approach for analyzing longitudinal data. In these models, a time curve is estimated for each individual in the study from the available data without imputation, which works well as a substitute for interpolation. If many patients have missing observations in the later stages of a study, there may be a considerable degree of extrapolation. In this case, the method must be used with caution.

More sophisticated methods for imputing missing values are model based. For example, regression models have been used where the variable with missing data is the dependent variable. Parameters in the regression equation are estimated based on data from complete records. The predicted value from the model is used as an estimate of the missing data value. Another approach relies on maximizing a likelihood function using the available data values while taking into account the nature of the missingness. Here great care must be taken in specifying the underlying distribution function of the random variables.

Perhaps the most widely used method of imputation is the expected/maximization (EM) algorithm. It was originally conceptualized as a method for finding maximum likelihood estimators for incomplete data. The algorithm starts by choosing initial estimates of the values of the unknown parameters. The estimates are improved iteratively by first computing the conditional probability distribution of the missing data given the observed data and then the current estimate of the parameters. The expectation of the log likelihood over the previously calculated distribution of missing values is obtained. This is called the *E step* of the algorithm. A new or updated estimate of the unknown parameters may be obtained by maximizing this expectation. This step is called the *maximization step* (M step) after which the E step is repeated. An important feature of the EM algorithm is that it gives the complete probability distribution for the missing data and point estimates for the model parameters. Under some reasonably general conditions, the EM estimates obtained in the iteration procedure converge locally to the MLE.

The methods described above handle missing data under the MAR assumption. Pattern-mixture models have been proposed for nonignorable missing data. Records are stratified into groups with different expected patterns of response and missingness. The group then becomes a predictor variable in a method of analysis (e.g., hierarchical linear models [HLM]) that allows subjects to have incomplete data across time. In this way the degree to which missingness influences outcomes can be assessed. Group membership can also be used in an interaction term in the model. This allows the assessment of the degree to which missingness patterns interact with key effect variables such as treatment group.

In sum, there is no one simple recipe for handling missing data. An understanding of the reason for the missingness is necessary, and a critical eye must be kept on the question of whether the MAR assumption is plausible. Whatever technique is used, some form of sensitivity analysis should be used to see how the imputation carried out in different ways affects the results. The choice of technique to use to handle the missingness must be made on a case-by-case approach.

SPECIFIC STATISTICAL METHODS

In this section, a variety of commonly used analytic techniques are introduced. These include linear regression and logistic regression, contingency tables, the general linear model (GLM), and survival analysis. In mental health research, outcomes are typically observed over time, and a discussion of longitudinal methods to address such situations is given.

Regression Models

Regression models quantify a relationship between a dependent variable and one or more independent, explanatory variables. A statistical model is complete only if both its functional and probabilistic form and its parameters are determined. The procedure for estimating the unknown parameters is known as *model fitting*. Historically, the dependent variable, say Y, is assumed to follow a normal distribution, and the hypothesized model relates its mean or expected value and a function of the independent variables, say x_1, $x_2,\ldots, x_k$. The data consists of an observation on independent and dependent variables on each of N subjects. The most common model assumes that the normal mean is a linear function of the explanatory variables. That is, it is of the form

$$E(Y) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k,$$

where the $k + 1$ Greek letters, α, β_1, $\beta_2,\ldots$, β_k are unknown parameters to be determined from the data. In terms of the actual observations rather than the expected value of Y, the form of the model is assumed to be

$$Y = \alpha + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k + \varepsilon.$$

Here ε represents a random error term that accounts for the deviations among the observations from their mean value. For each subject, the difference between the observation Y and the model fit evaluated at his or her specific value of the independent variables is called the *residual error*. If Y follows a normal distribution with mean $\alpha + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_k x_k$, and variance σ^2, then the error term is also normal with the same variance but with mean zero. In a regression analysis, estimates of the coefficients are obtained by maximizing the likelihood of the observations. Elementary calculus is used to find the value of the estimates, which are the solutions of a set of simultaneous equations, referred to as the *normal equations*. An alternative strategy for finding estimates of the parameters is to minimize the *sum of the squared errors* as a criterion for the goodness of the fit of the model to the data. The errors or the *residuals* are the difference between the observed values and the predicted values, the latter obtained by substituting the values of the *x*s into the regression equation. The *ordinary least squares* (OLS) approach makes no assumption as to the distribution of the error term. The method of OLS was developed at the turn of the 18th century by the mathematician Karl Friedrich Gauss working in Germany, and some historians say by others including Adrien Marie Legendre, Pierre-Simon Laplace, and (possibly) Robert Adrain, France and America, respectively. The least squares solution and the maximum likelihood solution are identical if the dependent variable is normally distributed.

Since specification of the set of explanatory variables is somewhat subjective, regression analyses include tests of whether each coefficient is equal to 0. If the null hypothesis is rejected, then the explanatory variable is included in the model. Stepwise procedures for choosing the variables to include in the model are also commonly used. Goodness of fit may be ascertained in a variety of ways, and model validation is a critical step in building a creditable model. At a bare minimum, the value of an R^2 statistic, which is the fraction of the total variability in the response that is accounted for by the model, should be obtained. But a high value of R^2 is not a guarantee that the model fits the data well, so it is wise to examine the residuals as well. Different types of plots of the residuals provide information on the adequacy of different aspects of the model. If the model fits well, a plot of the residuals will appear to behave randomly. This approximates the random errors that explain the difference between the independent variables and the response variable. If there is a nonrandom structure evident, then the model does not fit the data well.

There is, of course, no reason to limit the function on the right-hand side of the regression equation to linear forms. Many applications use rather complex nonlinear functions to represent the hypothesized relationships. In these cases, numerical methods are the only practical means for obtaining the estimates, and hypothesis tests are usually valid for large samples only. In the past quarter century statisticians have generalized regression models in many directions, and applications incorporating these extensions appear frequently in the psychiatric literature.

Classification: Logistic Regression and Machine Learning Techniques

Many research studies deal with outcome variables that are discrete. The simplest and most common case is dichotomous or binary random variables. A binary variable is often used to define the occurrence of an event, such as a treatment success, a treatment-emergent side effect from a study medication, the disappearance of a symptom, or death. The event of interest might also be a classification problem, that is, predicting membership in one of two groups. The random variable Y takes the value 1 with probability P if the event occurs, and zero with probability $1 - P$ otherwise. This is called a *Bernoulli random variable*, and an experiment in which many Bernoulli random variables are observed is called a *Bernoulli trial*. An investigator may want to know how other explanatory variables (covariates or risk factors) affect the frequency of the occurrence of the event. The idea is to use data, the training set, to find a method that will identify relevant covariates and use them to correctly predict an outcome in the test set. In recent years, there has been an explosion in the amount of available biologic information (genetics and epigenetics, imaging, peripheral neuroendocrinology, clinical self-report, etc.) that can contribute to the classification and prediction accuracy. The limitations of traditional data analytic methods in such circumstances, in which there may be many more potential predictors than subjects has led to the development of “big data” methods. In this section, after introducing classical logistic regression analysis, we introduce machine learning techniques, algorithmic methods that build models based on sample data that do not follow strict rule based or structured statistically modeling approaches.

Logistic Regression

Were the dependent variable continuous and approximately normally distributed, multiple linear regression would likely be used to explore its relationship to the covariates. Here, linear regression is not appropriate. An applicable model for a dichotomous variable is *logistic regression*. In this approach, the model assumes that the log of the odds ratio of the event occurring is linear in the covariates. These independent variables may be continuous variables, categorical variables, or both. The *odds* is the ratio of the probability that the event occurs to the probability that it does not occur. Odds are commonly used in gambling contexts. If the odds that a team will win are three to one, then one would expect the team to win about three times more often than its losses. In this case, the probability of winning is 3/4. Suppose q is the probability of the occurrence of the event. Then odds = $q/(1 - q)$ and q = odds/(1 + odds).

The logistic model is

$$\log q/(1-q) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k.$$

The left-hand side of the equation is called a *logit*. The covariates on the right-hand side of the equation can be continuous, dichotomous, nominal, or ordinal. Tests of the null hypothesis that each parameter is 0 may be made. Interpretations of the coefficients are made in a manner similar to ordinary linear regression. However, logistic regression calculates changes in the log odds of the dependent variable, not changes in the dependent variable itself, as in linear regression. For plotting and interpreting results from logistic regression, it is usually more convenient to express fitted values on the scale of probabilities. The inverse transformation of the model equations yields the logistic function for the probability of the event q.

$$q = \exp[\alpha + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k] / \\ (1 + \exp[\alpha + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k]).$$

The fit of a logistic regression can be assessed by looking at a classification table that displays whether the model has correctly classified each of the observed outcomes of *Y*. Goodness-of-fit tests are available as indicators of model appropriateness. One method begins by dividing the subjects into ten groups, in an increasing order of estimated probability of occurrence of the event. The first group corresponds to those subjects who have the lowest predicted probability; the next group corresponds to those with the next lowest predicted probability; and so on. A chi-square statistic is used to examine whether the observed counts in each group are close to the expected count under linearity. If they are, the chi-square statistic will be small and the corresponding *P* value will be large. Logistic regression can be extended beyond dichotomous response variables to ordered polychotomous (more than two) categories.

There are many measures of the accuracy of a classifier. The most widely used is the area under the receiver-operating (ROC) curve. The ROC graphically displays the true positive rate (sensitivity or recall) plotted against the false positive rate (1 - specificity, or fallout) at various thresholds. The area under the curve (AUC) from a sample data set is an estimate of the probability that the classifier assigns a higher score to a randomly chosen member of one class than to a randomly chosen member of the other class. The *P* value of a chi-squared test that this probability differs from ½, is often reported.

Supervised Machine Learning

In the classification setting, *machine learning* methods are shorthand for a collection of computer-driven approaches for obtaining a classification rule learned from training data. Among the many machine learning algorithms developed, two prominent and promising approaches, *CART* and its generalization *Random Forests* and *Support Vector Machines (SVMs)* are introduced below. These are popular and have been implemented in a number of software packages.

CART determines a set of logical if-then conditions, instead of a linear equation as in logistic regression, on predictor variables that corresponds to a logical or decision tree leading to terminal nodes.

CART, the abbreviation for the classification and regression tree algorithm, is based on *recursive partitioning,* is often able to uncover complex interactions among predictors or features that may be difficult or impossible to uncover using traditional multivariate techniques. The composition of the training set membership in a specific terminal node is used to estimate the conditional probability of class membership and to predict or classify all subjects in that node. For example, if 80% of the subjects in the node are in one group, then all subjects in the node, are classified, some erroneously, as members of that group. The feature on which to split and the value on which to split (e.g., age greater than 75) at each node is chosen by the software to produce the greatest improvement in predictive accuracy at each step. This is usually driven by a “node impurity” measure such as the Gini Index, which provides an indication of the relative classification homogeneity of subjects that fall in the terminal nodes. The general approach to limiting over-fitting is first to stop generating new splits when further splitting produces only a small improvement in prediction accuracy. The candidate prediction tree is subsequently parsimoniously “pruned back” to further avoid the use of more complex models than are required. An added possibility is the use of linear regression at the terminal nodes.

Random Forests. CART provides the underpinning of the Random Forests (RF) classification method. In the RF approach, a multitude of *decision trees* are constructed during the training phase. The individual trees in the “forest” are grown by taking a random sample of subjects. If there are many more candidate features than subjects, these too are sampled at random as well. The final probability that an individual with a particular vector of covariates is predicted to be a member of a class is by “majority vote,” that is, the average of the probabilities of the terminal nodes into which the predictor vector falls in each tree in the forest. This *bootstrap aggregating approach* is called *bagging* and its purpose is to reduce variance and to prevent overfitting. Each individual tree may be highly sensitive to noise, but model averaging across many trees reduces variability, under the condition that individual trees are not highly correlated. By selecting random subsets of features in growing the forest, referred to as “feature bagging,” correlations among trees is reduced.

Support Vector Machines. SVM algorithms build classifiers by identifying a linear decision surface that separates the classes with the largest distance, also called *gaps* or *margins*, between objects at the borderline. If there are two covariates, the space is two-dimensional and the decision surface is a line. Although an infinite number of lines can separate two classes, only one, called the support vector, uniquely separates classes with the largest gap between borderline objects. Often it is not possible to linearly separate sample objects belonging to two classes. When a linear decision surface cannot be identified, a SVM maps the data into a higher dimensional feature space in which a separating linear decision surface can be identified. This technique is known as the *kernel trick*, which extends SVMs beyond linear to nonlinear classification. This framework is particularly useful in the not uncommon situation in which the dimension of the features is extremely large. SVMs construct a hyperplane, or set of hyperplanes in high dimensional space, which separates the groups and determines the classification of a new subject. Support Vector Regression is an analogous procedure when the variable of interest is a real number instead of a class indicator.

Over-fitting. When there are hundreds or thousands or even millions of *features* under consideration, the potential for over-fitting is profound, particularly when the number of subjects is relatively small. With so many predictors available to use in fitting the model, the algorithms of most classification programs can achieve near-perfect results on the training set, but more often than not fail abysmally on the test set. Many techniques have been developed to avoid or at least detect this over-fitting difficulty while at the same time permitting utilization of the full range of potential predictors. These include evaluating the model’s performance on a data that is independent of the training set, for example, cross-validation, as well as methods that utilize fit criteria that penalize the use of increasing numbers of parameters and more generally, model complexity, for example, regularization and pruning. In a Bayesian framework, regularization is equivalent to imposing specific forms of priors on the parameters. Randomization tests are also used; the class membership in the training sets is randomly scrambled and the classification algorithm is applied. If good sensitivity and specificity are obtained for fictitious class labels, clearly, the algorithm cannot be trusted.

Contingency Tables and Log Linear Models

Many research studies involve discrete random variables. Frequency distributions of two discrete variables tabulated simultaneously are called *contingency tables*. The levels of one variable are listed in the rows of a table, the levels of the other variables are listed in the columns, and the joint frequency is entered in each cell. The sums of the cell frequencies across both the *r* rows and *c* columns are placed in the margins. The lower right-hand corner of the table displays the sum of the row marginal frequencies, which is equal to the sum of the column marginal frequencies, which is equal to the sample size.

Reports of many research studies begin with a description of the sample population, including the distribution of patient characteristics, such as treatment and baseline severity of illness. If there are two treatment groups being compared, then it is important to assess whether the groups were comparable at baseline. Define a treatment group indicator variable for the columns and a severity level variable for the rows. The question then is: Are the two variables independent or is there an association? Effects in a contingency table are relationships between the row and column variables in which levels of the row variable are differentially distributed over levels of the column variables. If the two variables are not independent, the two treatment groups have different distributions of baseline severity level, and the row variable will need to be controlled in any subsequent treatment comparisons in the analyses. Failure to reject the null means that there is not enough evidence to conclude that the variables are dependent; observed differences in cell frequencies are likely due to chance. Nevertheless, even if the test failed to reject the independence hypothesis, it may still be necessary to adjust for imbalances in baseline variables. Important prognostic variables may be sufficiently imbalanced to alter inference and cause statistical errors.

Hypothesis tests of association are often based on a chi-square statistic. The test statistic examines the difference between the observed counts in the table and those counts that would be expected if the variables were independent. The statistic sums the ratio of the squared difference between the actual count and the expected count to the expected count under the assumption of independence. If the differences are small, the data support the hypothesis that the variables are independent. In the 2 × 2 table, the difference of proportions, the relative risk, and the odds ratio are measures of the strength of association.

Contingency tables can involve more than two variables. One of the most common situations is the $2 \times 2 \times K$ table. For example, one variable may be treatment assignment to drug or placebo, the second may be a variable that measures success or failure, and the third may represent a control variable such as research sites, gender, or initial severity. There are three test statistics commonly used to analyze such tables. The Cochran–Mantel–Haenszel (CMH) statistic assumes a common odds ratio and tests the null hypothesis that two of the variables are conditionally independent, while controlling for the possible confounding factors of the rest of the variables. The odds ratio is a measure of the increase in odds of success for those given a drug relative to those given a placebo. If the odds ratio is 1, the drug has no effect. The CMH tests whether the response is conditionally independent of the explanatory variable (treatment assignment) while adjusting for the control variable (site). If the directions in some strata are opposite to the direction of those in other strata, the CMH statistics have low power for detecting an association. The CMH procedure first estimates a common odds ratio across the K strata and tests whether it is equal to 1. The

Breslow–Day statistic tests the null hypothesis of homogeneous odds ratios. That is, it tests whether the odds ratio between the assignment and outcome variables are the same for the *K* levels of the third control variable.

Higher level multidimensional contingency tables and more complex hypotheses are often analyzed using an approach known as *log linear models*. These models are used when two or more variables are measures of response rather than explanatory or control variables. The log linear model is one of the specialized cases of the generalized linear model, discussed below, for Poisson-distributed data.

The General Linear Model

The restriction to a normally distributed dependent random variable in regression theory was removed with the introduction of the GLM by John Nelder and Robert Wedderburn. This model assumes that the dependent random variable has a distribution in what is called a *parametric exponential family*. This family includes not only normally distributed and other continuous random variables, but also many discrete random variables such as the binomial and the Poisson. The latter distributions are used for modeling count data. The classical regression approach that models a normal mean as a linear function of the explanatory variables is generalized in GLM to a regression between a function of the mean and the explanatory variables. The function is called the *link function*. Although there are many possible link functions, associated with each particular parametric distribution is a natural or *canonical link function*, which enables efficient estimation of the coefficients. Here too, estimation is accomplished by maximizing the likelihood of the observations under the assumed parametric exponential family distribution via the link function. For example, in the case of a Bernoulli response variable with mean p, the canonical link function is $\log[p/(1 - p)]$, the log of the odds. Here, GLM assumes that the error term follows a logistic distribution, which is a member of the exponential family of distributions. But this is exactly what is done in logistic regression, which is therefore a special case of GLM. As in ordinary linear regression, tests of the hypotheses that coefficients of the explanatory variables do not differ from 0 are used to determine which ones have an effect on the mean. Similarly, if count data are distributed as Poisson variables and the link function is the log of the counts, then the GLM analysis is equivalent to a log linear model analysis of a contingency table.

Longitudinal Models

In the GLM and regression context, a single dependent random variable for each subject is considered. Especially in studies of mental and other chronic illnesses, subjects are usually observed at multiple time points or occasions. A typical hypothesis in such situations is that the means at all T time points are equal. This corresponds to the statement that there is no change over time. Conceptually, data in this situation may be described as a rectangular array, comprised of N rows and T columns. The rows correspond to the N subjects, and the entries in the columns are the subjects' response at the T time points. In a pre- and postmedication trial with N subjects, there are $T = 2$ columns. In the simplest case, the question is whether the mean effect of the pre- and postmedication responses are the same. A paired t, based on the difference between the pre- and postresponse is the usual statistic for this comparison.

Until fairly recently, the most common approach to analyzing longitudinal data was based on a *repeated measures* model. The statistical assumption for this model requires that the T random responses of each subject follow a multivariate normal distribution in which the covariance structure is completely symmetric. That is, the variances at each time point are equal and the covariance between any two responses, irrespective of their time difference, are equal. Clearly, these are rather demanding assumptions. Also, missing observation presented a significant problem, and in many trials all data on some subjects have been omitted. More recently, methods such as the EM algorithm enabled incomplete repeated measures data sets to be analyzed. However, hierarchical multivariate linear models, a generalization of repeated measures model have become more popular.

In a longitudinal study, despite the best of intensions, the occasions when subjects are observed as well as the number of time points that subjects are observed may vary widely from patient to patient. HLM allows such deviations, which overcomes the missingness problem when the data are MAR. While still retaining the multivariate normal distribution assumption for each subject, these models do not restrict the structure of the covariance matrix. The name hierarchical refers to the view that conceptually the analysis proceeds on different levels: Time is nested within subjects, subjects may be nested within sites, sites may be nested within countries, and so on. The model posits that the random normal observation is a sum of three terms: (1) a sum of the form, $\alpha + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_k x_k$, (2) a sum of random effects, and (3) an independent error term. The first sum is referred to as the *fixed effects* term. Although the random effects comprising the second sum are not observed, they enter the model by contributing to the variances and covariances of the variables. Since subjects are independent, the form of the likelihood is a product, which leads to a set of extended normal equations for estimating the parameters. Parameters may also be estimated using a least squares approach, although within this model a generalized least squares criterion, that weights the residuals in terms of variances and covariances, is used.

In a still more recent development, the multivariate normal assumption has been relaxed through the introduction of a *semiparametric regression* method, which incorporates elements of the GLM. The method of generalized estimating equations (GEE), introduced by King-Yee Liang and Scott Zeger, focuses on the means at each time point through link functions. In this way, each marginal mean response at each observed occasion is modeled. In many psychiatric studies, hypotheses are concerned with the behavior of marginal means. In lieu of modeling the entire joint distribution of the observations over time, the GEE method models only the variance and covariances of the observations over time. The variance at a given occasion is modeled as a function of the marginal mean at that occasion. The method allows missing data provided they are MCAR, that is, they are MAR conditional on the covariates. Although the likelihood function cannot be formed because the parametric form of the distribution is not specified, estimators can be obtained by solving an analogue of the normal equations. The resulting estimators are consistent. That is, as the number of subjects increases, the estimators converge to their true values. Consistency holds even if the structure of the correlation matrix has been misspecified. Also, asymptotically the distribution of the estimators is normal, so that testing whether the coefficients of the independent variables differ from 0 can be accomplished.

Latent Class Growth Analysis and Growth Mixture Modeling

A constantly occurring research question is identification of distinct patterns of longitudinal course and outcome of a disease and the differential characteristics of individuals who follow them. For example, individuals’ response to trauma varies; many resilient individuals rapidly remit, some are slow remitters, some are nonremitting and some “late-onset” victims display low symptom levels initially that increase over time. Latent Class Growth Analysis (LCGA) and Growth Mixture Modeling (GMM) are commonly used statistical methods for identifying trajectories and the associated covariates associated with class membership. GMM extend traditional growth curve modeling, which allows the intercept and slope parameters to vary across individuals. However, growth curve modeling assumes a common pattern of change across the population. In the case of GMM, the latent, that is, the underlying but not directly observable, variables that characterize the time course (the growth curve model, such as the slope and intercept) are utilized to identify an additional second-order categorical latent variable, class membership. Each class has its own growth model with unique covariance structure. The distinction between LCGA and GMM is that the former assumes that the variance and covariance among the growth factors within each class can be set to zero; that is the trajectories of class members are homogeneous. Because of complexities in model identification, analysts often begin with LCGA and constraints on the variance are removed as the search for a best fitting model proceeds. A typical data set is comprised of repeated measures across multiple time points and if data are missing at random, MLE is valid. A trajectory assumed to have a linear form requires, at a minimum, observations at three time points. A trajectory with quadratic term requires at least four time points. Maximum likelihood parameter estimates are obtained iteratively through the use of the EM algorithm. In these models, appropriate model selection methods need to applied to guard against misspecification or over-fitting. Omission of influential variables, inclusion of irrelevant variables, incorrect model form, errors-in variables, incorrect covariance matrices and heteroscedasticity are just some of the issues that need to be considered.

Survival Analysis

Many psychiatric issues are related to events in the time domain, for example, time to onset of effect of a treatment, time in hospital, and time to remission of symptoms of depression. These are generically called *time-to-event* or *survival* variables. The first survival variable that was studied was time to death. *Life table methods* were originally devised for actuarial and insurance uses to describe expected survival time. For a particular group of persons (e.g., males) and selected age intervals (e.g., decades), life tables usually exhibit the number of persons entering the age interval alive, the proportion of these who die in the interval, and the proportion for whom data became unavailable during the interval. The proportion who die in the interval is called the *hazard rate*. Other useful statistics that can be derived from such tables include the *conditional survival rate* (among those who enter the interval, the proportion surviving beyond the interval) and the *survival function* (the cumulative proportion of individuals surviving to the end of the interval). The *survival distribution* is defined to be 1 minus the cumulative distribution function, 1 − F(*x*). The time at which the survival function is equal to .5, the *median survival time*, is the statistic most often used to characterize the distribution. Other percentiles are of course of interest as well. Although life tables provide a great deal of information, they are of little use for predictive purposes or for assessing the impact of other variables on survival.

Sophisticated statistical methods for estimating survival time distributions were developed primarily to model data from clinical trials of cancer treatments, and even more sophisticated methods have emerged in association with the study of acquired immunodeficiency syndrome (AIDS). Survival time methods are widely used in most of the medical and biologic sciences as well as in engineering (where the method is called failure time analysis) and in the social and economic sciences. The methods for estimating survival time frequency distributions from sample data have been developed to take into account the possibility that persons may still be alive at the end of the study period. Such individuals in essence have missing data as to the time of their death, but it would be folly to exclude them from the analysis. Observations on these individuals as well as the times of those who dropped out of the study before the signal event occurred, for example, a subject has moved and contact is lost, are called *censored observations*. If a new treatment is designed to study recurrence of depression and the study lasts 2 years, a censored observation at study completion or at loss to follow-up indicates that the treatment has been successful at least for that period of time. As in the missing data situation, analysis of these latter types of censored observations is facilitated if the data are MCAR, and, are therefore, noninformative as to the distribution of the time to the event being studied. Nonignorably missingness such as systematic censoring, if erroneously assumed to be MCAR, may greatly bias the estimation of the survival time distribution.

The Kaplan–Meier survival function estimation technique is nonparametric because it makes no assumption as to the underlying shape of the distribution. Based on the observed survival times and censoring times, it defines time intervals that contain exactly one observed case (except if there are ties). This is in sharp contrast with life table methods that count the number of deaths in fixed time intervals. The probability of surviving beyond time *t* is the product of the probability of being alive in each interval up to time *t*. If a case is censored at some time point, it is used in the calculation of the estimated probabilities up to the time of censoring and not used in subsequent calculations. Survival distributions generated from two samples, such as two treatment groups, can be compared statistically. The most commonly used tests are nonparametric, including Gehan test, the generalized Wilcoxon test, and the log-rank test.

Parametric survival methods assume an underlying shape of the survival distribution, for example, exponential, Weibull, or Gompertz. Techniques such as MLE or least squares to fit the parameters of the model from the observed data are used to estimate parameters' values.

Many research projects entail an investigation of the influence that covariates have on survival time. Cox proportional hazard models were introduced to enable regression-type analyses to be conducted on time-to-event data. No assumptions are made concerning the underlying form of the survival distribution, so the method is called *semiparametric*. The model assumes that the hazard rate, the probability of dying at time *t* given one is still alive up to that time, is equal to a fixed population or underlying hazard rate multiplied by the exponential of a linear function of the covariates. The log of the exponential multiplier is a linear sum of the covariates. The multiplicative form of the model implies that the hazards are proportional. This is called the *proportionality assumption*, which explains the name of the method.

Proportional hazard models are frequently used to test the null hypothesis of equality of the survival distributions of two treatments. If there is reason to believe that there is a common underlying hazard function for the two groups, a treatment group assignment term is used as a covariate and the null hypothesis that the corresponding parameter is zero is tested. If there is reason to believe that each group has its own underlying hazard, a stratified analysis may be used to test the null hypothesis that the same regression model applies to the two groups.

Cure models have been proposed to account for situations in which the event being studied cannot occur for some part of the population. Cure models were introduced in cancer studies in which time to death was the principal outcome variable, but some fraction of the population was cured. In essence, there are two populations: Those who when given the test treatment will be cured and those who will die from the disease. In a genetics context, these are the susceptible and nonsusceptible groups. In psychiatry, the study of onset of treatment effect parallels this situation. In a study of the effectiveness of an antidepressant, an important parameter is the time for the treatment to take effect. But some in the population may never respond to the treatment and therefore will never have onset. This group is analogous to the cured group in the disease model. The quantities of interest in this model are the proportion cured and among the group not cured, the conditional probability of surviving to time t. For onset, the analogous quantities are the proportion of nonresponders, and among the group of responders, the conditional probability of onset by time t. The estimation of these quantities must be made with care. A subject may survive beyond the end of the study either because he or she is cured or because he or she has a true survival time that exceeds the time that observations cease. The proportion not cured may be estimated nonparametrically by the proportion still surviving at the end of the trial, as estimated in the Kaplan–Meier approach. The Kaplan–Meier curve can also be used to solve for the conditional survival distribution of the population not cured. If two or more groups are being compared, parametric and nonparametric models can be used to test for the equality of the cure fraction and for the equality of the conditional survival distribution. The advantage of parametric cure models is that they can include covariates that affect either the proportion not cured, or the conditional survival distribution, or both. Thus, one can learn about treatment effects as well as the characteristics of a group that predicts cure as well as those that predict shorter or longer survival time.

STUDY DESIGN

Usually, in the pursuit of a research question, there are many ways to design a study to estimate parameters and to test hypotheses. In all fields of inquiry, but in medical research in particular, an experiment must be designed so as to produce the most accurate possible estimates of treatment effect within the limitations of sample size and personal safety. To use a design that is less than optimal is certainly inefficient but also may very well be unethical. The study of the design of experiments is a field of inquiry in statistics that searches for designs that are as efficient as possible. This section examines only one issue, the design of a crossover trial, as an illustration of the kind of considerations that enter the search for optimality.

Crossover Designs

There has been much interest and indeed controversy about the use of crossover designs. In a crossover trial, the comparison of t study treatments is accomplished by observing N subjects on several occasions, usually called periods. A subject may receive a different treatment in each period, or one or more treatments may be repeated, so a subject acts as his or her own control. The best-known crossover design is a two-treatment, two-period, two-sequence trial in which each subject receives both treatments, some in the order AB and the rest in the order BA. Experimental designs in which subjects are crossed over to other treatments have long been recognized as having considerable potential for achieving greater precision than can be obtained from parallel groups (also called completely randomized) designs. This is because between-subject variation is eliminated from the error term. Another advantage is that a crossover design requires fewer subjects to obtain the same number of observations. In a two-period design, each subject contributes two observations. For some types of studies, it is expensive to recruit participants, and once one has been trained in the details of the study procedure, there may be high motivation to continue to obtain observations on the response to other treatments. Although they have not been used frequently in psychopharmacology, their use may well increase as the value of crossover designs is more widely appreciated by psychopharmacologists.

The negative aspect of crossover designs is the possibility that carryover or residual effects, that is, the effects of the previous treatment, whether pharmacologic or psychological, may alter subsequent responses. The standard analysis of a two-period, two-treatment, two-sequence design (AB, BA) is rife with problems. An FDA advisory committee compared this simplest of crossover designs, in terms of precision and cost, to the completely randomized one-period design. Byron Brown, a member of the committee, concluded “the crossover experiment can yield great savings in cost if the assumption of no carryover effect is valid, but the design should not be used if this assumption is in doubt.” In many cases, the sample size needed to test whether there is carryover present exceeds the sample size needed for a similarly powered parallel groups trial. For many years, the crossover design (AB, BA) was in disfavor, particularly by researchers in the pharmaceutical industry, as a result of Brown’s analysis and the presumed concurrence of FDA statisticians. However, enlarging the number of sequences to four so that the two-period design is (AB, BA, AA, BB) avoids the carryover problems of the (AB, BA) design, albeit with diminished efficiency to separate treatments. However, expanding the number of periods results in designs without the inefficiency of the two-period designs. These results have led to considerable renewed interest in finding ways to capitalize on the known advantages of crossover designs with three or more periods without falling prey to the problem of carryover. But there are many sequences possible, even for a three-period, two-treatment design there are eight possible sequences: (AAA, AAB, ABB, BBB, BBA, BAA, ABA, BAB). If there are to be *N* participants in the trial, how should they be allocated to each sequence to achieve the maximum possible efficiency in estimating the parameters that characterize the treatment effects? In a *P* period crossover design, there are *P* responses from each subject, which naturally are correlated. If the $p \times p$ covariance matrix of the responses is known, then the optimal design can be exactly determined. But this is hardly ever the case, and ignorance of the covariance matrix greatly complicates the problem of specifying an optimal design. There are two practical approaches to solving the design dilemma. (1) Based on information from other similar studies, the researcher can assume that the correlation structure is of some specified form, from which an optimal design may be determined. Almost all medical research involving crossover designs has been conducted under some assumption as to the form of the covariance matrix. In this case, the design is called *fixed* because the entire design is specified before the clinical trial begins. (2) A clinical trial with P periods can commence, and as data accumulate the information on the first few of the N subjects to be studied can be used to estimate the covariance matrix. Treating the estimate as if it were the true covariance matrix, the optimal sequences to which the next few subjects will be allocated are determined. Their data are added to the first set of data, and a new estimate of the covariance matrix is obtained. The process continues until all N subjects are studied. For reasonable sample sizes, simulated experiments suggest that the resulting trials are nearly as efficient as the optimal design that would have been used had the covariance matrix been known. Designs in which no specific form of the covariance matrix is assumed are called *response-adaptive* because the subsequent course of the design is specified only after prior responses are obtained.

Notably, the controversy over the use of crossover designs has not subsided. Optimality, results are based not only on the assumed covariance matrix but also on the assumed response model, that is, the set of assumptions as to how carryover and response are related. Different models may yield entirely different results. For example, some authors maintain that the carryover effect that occurs if two consecutive treatments are identical, for example, AA, is not the same as the carryover effect that arises from two consecutive treatments that are different, for example, AB. Recently, statisticians have begun to consider response models that reflect this and other views, and designs that are optimal under some of these models have been found.

EVALUATING TREATMENTS UNDER CONTROLLED CONDITIONS, IN THE REAL WORLD, AND UNDER FINANCIAL CONSTRAINTS

Efficacy studies, designed to determine whether a treatment has an effect, are usually carried out under relatively pristine laboratory-like conditions with rigid adherence to detailed protocols. In contrast, *effectiveness studies* attempt to evaluate how and if a treatment works under real-world conditions. Invariably, treatment choices must involve their costs. Statistical *cost-effectiveness analysis (CEA)* provides information to help support the decision maker.

Efficacy Studies

Randomized double-blind, controlled clinical trials are the gold standard for efficacy studies, enabling, theoretically at least, an unbiased assessment of the relative merits of the study treatments and causal inference. In an efficacy study, extraneous variables that might have an impact on outcome and therefore confound the results and their interpretation are controlled to the greatest extent possible. But when experimental trials are conducted under the best of laboratory-like conditions, it must be kept in mind that the ability to generalize the findings is limited. Such trials provide little evidence as to how the study treatments will work under usual care conditions in the real world. Efficacy studies are usually conducted in a limited number of well-circumscribed patient populations, and many of the patients most likely to receive the treatment if the FDA approves it are excluded. Trial eligibility criteria may exclude, for example, patients with comorbidities, those whose symptoms are too severe or not severe enough, those suspected or known to be “noncompliant,” or those who have a history of violence. The trials may involve care conditions that are quite specialized, delivered by highly trained staff who provide individual attention far in excess of the norm. A positive finding does prove that the experimental treatment works, but the issue of efficacy beyond the well-defined populations on whom it has been tested in the well-defined environments in which the studies were conducted remains open.

Effectiveness Studies

Effectiveness studies examine how well a treatment works under real-world conditions. Many studies designed as randomized clinical trials should actually be considered to be effectiveness studies, and the environmental deviations from controlled conditions should be taken into account. For example, clinical trials of psychotropic agents are rarely conducted under pristine experimental conditions. They may take place for a short time in hospitals, but follow-up is usually in an outpatient setting. They may be based in outpatient clinics or in multiple practitioners' offices so subjects come and go from their homes. They may have multiple exposures to various unreported risk factors that impact the conditions for which they are being treated. Such conditions cannot be completely controlled. Over the course of the study, treatment groups may be differentially affected in ways that can influence outcomes to such a degree that the effect of the treatment they receive is overwhelmed.

Although randomization is preferred, this may not always be possible; many studies are conducted in which patients have been assigned to treatments in the naturalistic course of their care. Although methods for mimicking randomization (e.g., propensity scores) can be used, findings from these studies are often affected by environmental factors unrelated to the study treatment. Sometimes study treatment and locus of care are confounded because of the nature of the intervention. This is almost always true in trials that test nonpharmaceutical treatments, such as new clinical programs, screening models, or complex approaches such as supported housing. In such trials, blinding as to treatment assignment is essentially impossible so that the assumption of unbiased assessment of outcomes may be questionable.

Such situations create studies in which analysis of the data and more importantly their interpretation are substantially more complex than analyses of the traditional randomized, double-blind controlled clinical trial. Nevertheless, the value of these studies can be enormous. Besides having the potential to provide information on efficacy, a well-designed effectiveness study can discover the way to maximize the yield on the use of an efficacious agent under real-world conditions. These studies test acceptability both to consumers and to the health professionals who deliver the treatment. Outcomes of interest include measures of the treatment's acceptability to recipients and to caregivers, the treatment's impact on quality of life, and its costs. Compliance issues need to be examined with respect to events in the clients' world and to the biologic or structural elements of the intervention itself. To understand the factors that affect compliance, data should be collected on basic demographic descriptors and on substance use, work and housing conditions, social relations, and environmental conditions, including those of the caregiver and the treatment setting. Such data items need to be collected at baseline and also over the course of the study.

From a statistical perspective, multiple analyses of multiple outcomes are required. In the comparison of treatment groups based on an intent-to-treat analysis, all subjects, including noncompliers, treatment crossovers, and dropouts remain members of the group to which they were originally assigned. This analysis provides a view of how well the "policy" of assigning the study treatments works in the real world, blemishes and all. An efficacy analysis can be conducted using the same data set by identifying matched persons from each group based on predicted treatment assignment, compliance, or crossover behavior patterns. Treatment outcomes are compared within matched groups. Propensity score methods can be used to accomplish the matching. A third set of analyses might examine the impact of environmental factors on treatment acceptability and compliance.

Cost-Effectiveness

The high cost of health care provides a compelling reason to examine the costs of interventions, not just their effectiveness. CEA is an economic technique for guiding choices among alternative treatments, policies, or program-level interventions so as to maximize effectiveness under a constrained budget. In a cost-effectiveness (CE) study alternative interventions are compared in terms of the costs required to provide a particular level of effect.

For CE purposes, a program *P* is characterized by an ordered pair of positive values (ε, γ), representing respectively its mean effectiveness and its mean cost. Programs are *mutually exclusive* if only one of them may be used at one time in one patient. However, a mixture occurs when two or more mutually exclusive treatments are given to a collection of subjects. For example, if 100 patients are to receive medication treatment A or B and no person can receive both treatments because they are incompatible, then 80% receive drug A and 20% receive drug B, a mixture of programs has occurred. Programs are *independent* if any number of them may be used at one time and neither the cost nor effectiveness of any program is affected by a decision to use or not use any other program(s) in the set. A program is *dominated* if there is another program with greater or equal effectiveness and less cost. A *weakly dominated* program is one that is dominated by a mixture of programs. Within a class of mutually exclusive programs, only those that are neither dominated nor weakly dominated (the admissible class) should be considered for use. The *cost-effectiveness ratio* (CER) of a program, the price per unit of effectiveness, is the ratio γ/ε. If two programs are ranked in order of increasing cost, the *incremental cost-effectiveness ratio* (ICER) of the program with higher cost compared to the program with lower cost, the additional price per additional unit of effectiveness, is the incremental cost divided by the incremental effectiveness.

Subject to conditions on independence and mutual exclusivity among specified programs and *given the values of their mean cost and mean effectiveness*, the *deterministic* resource allocation problem of CEA is the selection of a set of programs for funding whose effectiveness is the maximum that can be achieved without incurring a cost greater than a specified fixed budget, C^*. For independent programs, resources are allocated sequentially in order of increasing CERs until the budget is exhausted. For mutually exclusive programs, *dominated* programs are eliminated and the remaining programs ranked in order of increasing effectiveness, ICERs are computed, weakly dominated programs are eliminated, ICERs are recalculated, and the process continues until all remaining programs are admissible. The remaining programs form the *frontier*, the piecewise line segments connecting adjacent admissible programs. Given a budget constraint, the program that should be funded is the one on the frontier with that budget; if the budget lies between two frontier programs budgets, then a mixture of these two is funded.

When analyzing CE from the societal perspective, the above fixed budget approach is replaced by a fixed price approach. Economists have shown that the greatest feasible health gain is achieved by implementing within each independent set of mutually exclusive programs that program whose ICER is largest among those programs that do not exceed a specified threshold value. This value, denoted by λ, is interpreted as the amount society is willing to pay (WTP) for an additional unit of health gain. Programs with ICERs above the threshold value are not implemented. The fixed budget and fixed price approaches prescribe the same allocation, except that the latter does not allow partial or mixture implementations of programs.

Statistical methods specifically for CEA began to emerge in the mid-1990s centered on methods for obtaining CIs for ICERs. The inherent difficulty of dealing with a random ratio whose denominator may assume the value 0 compounded the difficulties of this approach. Recently, the value of net health benefit (NHB) for statistical CEA has become widely accepted. The *NHB* of program k is defined as $\mathrm{NHB}_k(\lambda) = \varepsilon_k - \lambda_k/\lambda$, $k = 1, 2, \ldots, K$. At each WTP value, λ, the optimal NHB rule for mutually exclusive program funds the program with the largest positive NHB. For resource allocation, both the standard ratio-based allocation rules of CEA and the new NHB-based rule, lead essentially to the same optimal solution.

The NHB rule requires neither rank ordering of programs nor elimination of inadmissible programs, which enables statistical methods that control errors and that emulate the optimal deterministic rules of CEA. For bivariate normally distributed cost and effectiveness variables and a specified WTP, λ, the statistical procedure is based on the method of *constrained multiple comparisons with the best* (CMCB) for determining the program with the largest NHB. This method both controls the pointwise error rate at each λ and provides a confidence set for the programs that are either best or comparable to the best. The statistical frontier, plotted in the λ-NHB plane, displays the program or possibly the set of programs with the largest NHB at each WTP value. Bayesian methods for performing a CEA have also been developed.

Theories of Personality and Psychopathology

6.1 Psychoanalytic Theories and Treatment: Perspective from North America and Great Britain

SYLVIA GONZALEZ CRUZ, M.D., SHWETA SHARMA, PSY.D., CYNTHIA MULDER, L.C.S.W.S., AND DEEBA ASHRAF, M.D.

Psychoanalysis is over a century old. It is a deep, independent, intellectual tradition that has continued to make significant strides in its understanding of human subjectivity. It is a body of scientific knowledge based on fundamental theoretical propositions and an ever-increasing fund of information derived mainly from intensive clinical work with patients. Whether for or against psychoanalytic ideas, the biologic psychiatrist of today cannot afford to ignore unconscious motivation, defenses, early childhood experience, dynamics of repetition compulsion, and the myriad of other psychoanalytic discoveries that complicate, if not outrightly, challenge the mainstream understanding of mental disorders.

Psychoanalysis is also a method of investigation. It is unparalleled in the depth of its inquiry into human experience. Psychoanalytic epistemology allows it to study and explore the most complex human problems and offer a perspective that complements the biologic understanding of human development and psychopathology. As a therapeutic technique, psychodynamic psychotherapy is an evidence-based approach to treating mental disorders based on psychoanalytic ideas that are well-recognized and widely practiced in several parts of the world.

Psychoanalytic theories are ambitious formulations aiming to expand our understanding of human development and suffering. They add explanations of unconscious meanings and influences. Each psychoanalytic theory makes a unique contribution regarding the understanding of unconscious mental functioning and its clinical manifestations. This chapter aims to give a basic understanding of psychoanalytic models of mind that generations of clinicians have arrived at, mainly through intensive study of private thoughts and feelings in the context of an intensive psychotherapeutic relationship. These models represent a vibrant body of ideas that reward detailed study. However, the vastness of the ever evolving and expanding psychoanalytic thinking is near impossible to summarize in a chapter. For pragmatic reasons, this chapter will focus on psychoanalytic thinking from the major North American and British traditions and leave out the developments rooted in French, German, Italian, and Latin American traditions. We hope that the introduction we provide will get interested readers excited to know more. The chapter assumes no prior knowledge of psychoanalytic theories. However, it is intended for readers interested in the clinical practice of psychoanalysis and psychodynamic psychotherapy.

To help orient the readers to extremely rich but often complex and sometimes confusing psychoanalytic ideas, we begin with what is common among various psychoanalytic theories. All psychoanalytic theories share the following common set of assumptions:

- Complex unconscious mental processes motivate and determine human behavior, affect regulation, and adaptation to the social

environment. All conscious human action is influenced by an unconscious desire for instinctual gratification or safety.
- All psychological events, including behaviors, feelings, thoughts, and actions, are influenced by and are the end result of a preceding sequence of causal events.
- All psychiatric problems can be meaningfully analyzed by considering unconsciously held beliefs and feelings that determine an individual’s reaction to their biologic, psychological, and social problems. In other words, symptoms carry multiple meanings that are hidden and unconscious.
- Intrapsychic conflict due to incompatible wishes or adverse childhood experiences is ubiquitous.
- Defense mechanisms are part of normal human development and work to protect the self against threat to safety and unpleasure.
- Interpersonal experiences are internalized and determine the representation of self and others.
- The therapeutic relationship is an essential mechanism of change in treating the suffering mind.

SIGMUND FREUD

Freud gave meaning to mental disorders by linking them to childhood experiences. He developed his theory over several decades. Three main assumptions helped Freud organize his thinking as he revised his theory into successive models of the mind —*psychological determinism, unconscious psychological processes,* and *unconscious psychological conflicts*. The assumption of psychological determinism, derived from Freud’s Helmholtzian convictions, allowed him to develop a causal psychological understanding of apparently arbitrary pathologic behavior. His belief in psychological determinism was reinforced by his clinical observation that apparently meaningless hysterical symptoms could be relieved when linked to repressed past experiences. The assumption of unconscious psychological processes allowed Freud to bring unconscious processes within reach of psychological understanding and explanation. Freud used first hypnosis and then free association to make patients aware of the repressed unconscious past experiences. He found that the unconscious mental processes differed radically from conscious behavior and thought processes in the manner of their regulation. The unconscious material is governed by the pleasure principle and the mechanisms of the primary process as opposed to the secondary process. He discovered that the unconscious psychological conflict between and among psychic forces formed the basic elements underlying neurotic difficulties.

The Trauma Hypothesis

Freud's first major psychoanalytic proposal concerned the nature of hysterical illness. From 1887 to 1897, Freud was immersed in the serious study of patients with *hysteria*. His patients, primarily women, were experiencing physical symptoms like paralysis or blindness with no apparent organic cause. In collaboration with Josef Breuer, he extended the work of French neurologist Jean-Martin Charcot and demonstrated that physical symptoms of his patients were related to the psychological experience of trauma. This approach contrasted with the contemporary understanding that hysterical illness was due to the degeneration of the nervous system. Freud's proposal assumed that his patients had experienced emotional trauma that had become blocked from their awareness because it was unacceptable to their conscious mind. He described this state of dissociated consciousness as the basis of hysterical illness. He postulated that repression of an idea from consciousness and its exclusion from any modification by association with other ideas was an essential condition for the development of symptoms of hysteria. He held that even though out of consciousness, the emotions induced by the traumatic experience continued to press for discharge into consciousness and caused the patient to develop symptoms.

Freud believed that the traumatic experience of his patients generally involved childhood or early adolescent experiences that had aroused feelings that could neither be sufficiently expressed nor resolved. Invariably, when inquiring into past histories of his patients with symptoms of hysteria, Freud found that the repressed traumatic memories had to do with sexual experiences, usually recalled in the form of a sexual seduction occurring before puberty and often relatively early in the child's experience. He concluded that these early traumatic experiences or a series of experiences had been repressed because of their painful or disagreeable nature. However, the excitation involved in sexual stimulation was not extinguished, and traces of it persisted in the unconscious in the form of repressed memories. Freud held that these memories could remain without pathogenic effect until some event, for example, a disturbing love affair, served to revive them. At that juncture, the repressive counterforce's strength was diminished, and the patient experienced what Freud termed the *return of the repressed.* The original sexual excitement was revived and found its way by a new path, allowing it to manifest itself in the form of a neurotic symptom. Specifically, in conversion hysteria, impulses that were not allowed access to consciousness were diverted into paths of somatic innervation, resulting in such hysterical symptoms as paralysis, blindness, disturbances of sensations, and other manifestations. Freud observed that the symptoms of hysteria disappeared when the traumatic event was brought to consciousness, with the patient describing the event in great detail and putting the accompanying affect into words. In this model, the symptom was viewed as a compromise between repressed wish and the ego seeking to keep the repressed idea of consciousness. The process of repression thus involved conflicting forces, the repressed idea struggling to express itself and the "dominant mass of idea constituting the ego." Moreover, the therapy allowed strangulated emotion to discharge through conscious speech by remembering the repressed trauma and integrating it into consciousness.

Based on his clinical work, Freud reconstructed the following sequence of hysteria development:

1. The patient had undergone a traumatic experience. By trauma, Freud meant an experience that stirred up intense emotion and excitation, which was intensely painful or disagreeable to the individual.
2. The traumatic experience represented to the patient some idea or ideas incompatible with the “dominant mass of ideas constituting the ego.”
3. This incompatible idea was intentionally dissociated or repressed from consciousness.
4. The excitation associated with the incompatible idea was converted into somatic pathways, resulting in hysterical manifestations and symptoms.
5. What was left in consciousness was merely a mnemonic symbol only connected with the traumatic event by associative links that were disguised.
6. If the memory of the traumatic experience could be brought into consciousness and the patient could sufficiently release the strangulated affect associated with it, the affect was discharged, and symptoms disappeared.

Freud’s early research into hysteria led him to the striking aspect of psychoanalytic understanding; the seduction experiences were of central importance for understanding the etiology of not just hysterical illness but all neurosis. Freud attributed the basic etiology of the neuroses to sexual factors. Over several years, he continued to collect clinical material that seemed to reinforce this critical hypothesis. Freud extended the basic proposition based on the studies of cases of conversion hysteria that symptoms resulted from a compromise between a repressed impulse and other repressing forces to obsessive-compulsive phenomena and even to paranoid ideation. The logical consequence of this hypothesis was that the treatment focused primarily on enabling the patient to recall repressed sexual experiences. The accompanying excitation could be allowed to find its way into consciousness and be discharged along with the revivified and previously dammed-up affects. At this early stage, Freud believed that psychotherapy achieved its curative effect by ending the emotional force of the idea that had not been sufficiently abreacted in the first instance. Of note, Freud did not regard all hysterical symptoms as psychogenic in origin, so they could not all be effectively treated by a psychotherapeutic procedure.

The trauma hypothesis proposed a physiologic model of mind. Freud regarded repression as intentional and thought it served as the basis for converting a sum of neural excitation. When cut off from more normal paths of psychic association, this sum of excitation found its way even more easily along a deviant path leading to somatic innervation. He argued that the basis for such repression must be a feeling of displeasure derived from the incompatibility between the idea to be repressed and the dominant mass of ideas constituting the ego. Freud's collaboration with Josef Breuer brought about the publication of their *Preliminary Communication* in 1893. The *Preliminary Communication* created considerable interest and was followed in 1895 by *Studies on Hysteria*, in which Breuer and Freud reported on their clinical experience in treating hysteria and proposed a theory of hysterical phenomena. The case of Anna O. provided a critical starting point for Freud's thinking and a crucial juncture in the development of psychoanalysis. Freud's case discussions proved highly significant since they formed an early expression of his early psychoanalytic thinking and technique.

Although Freud quickly abandoned the trauma hypothesis and effort to provide a neurophysiologic model of the mind, many of his prescient ideas have been confirmed by the advanced neurobiologic research of the past few decades. The impact of the trauma hypothesis on the clinical practice of psychiatry can be felt to this day. Both the search for early trauma and the release of pent-up emotions remains part of the popular understanding of psychotherapy. However, at the time, Freud assumed that his patients' reports of memories of actual experiences represented unconscious fantasies. He believed that the counterforce of repression and resistance clashed with the sexual drives and diverted them into fantasies or symptoms and unconscious repression and resistance opposed these fantasies from becoming conscious. This led him to develop the topographical model of the mind.

The Topographic Model

By the turn of the twentieth century, Freud discovered the role of the child's own psychological experience in elaborating the memories of childhood seduction and associated mental contents. He learned that his patients' accounts of forgotten but revived memories of childhood sexual involvement were sometimes fantasies related to unconscious wishes and not consistently accurate. This forced Freud to turn his attention to the inner fantasy life of the child. He began to focus on the innate drives as the motivating force of personality development and distortion of this development in psychopathology. This approach marked the significant shift of attention in psychoanalytic thinking from external events as causes of disorder to drives (biologic tension states) pressing for discharge and gratification against the resistance of consciousness. In this model, Freud understood dreams and *parapraxis*, so-called slips of the tongue, as the indirect or inadvertent expression of the blocked drives or wish fulfillment. In topographic formulation, the psychotherapeutic intervention was to lift the repression, making conscious the unconscious wish.

The Three Systems of the Mind. Beginning with the abandonment of the trauma hypothesis and the concomitant turning of Freud's interests to inner processes of fantasy and dream formation, Freud's thinking was mainly cast in terms of the topographic theory. In the topographic viewpoint, mental events were classified descriptively regarding the quality and degree of awareness. In constructing his psychological model of dreaming, Freud distinguished three layers of mind—*system unconscious*, *system preconscious*, and *system conscious*. These systems were described not in anatomical or spatial terms. Instead, they were specified according to their relationship to consciousness.

The *system unconscious* or dynamic unconscious, the deepest layer of the mind, was thought to be made up of wishes and drive representations that were in some measure unacceptable, threatening, or abhorrent to the individual. Freud held that these wishes, and drives were primarily sexual and sometimes destructive. Specifically, at this stage of theory development, Freud considered drives to consist of sexual and self-preservative (ego) drives—aggression was added later. The system unconscious was assumed to be regulated by the *primary process* demands and the *pleasure principle*. The primary process had as its principal aim the facilitation of wish fulfillments and instinctual discharge.

Consequently, it was intimately associated with—and functioned in terms of—the pleasure principle. System unconscious disregarded logical connections, permitted contradictions to coexist, recognized no negatives, and had no conception of time. The unconscious mental contents of the system are inaccessible to consciousness, except indirectly or inadvertently. Freud identified dreams as the product of primary process thinking. He also held that the quality of motility, characteristic of primary process thinking and unconscious energy, was linked to the capacity for creative thinking. The current understanding of dreams, based on the neuropsychological studies by neuropsychoanalyst Mark Solms, discussed later in this chapter, validates Freud's classical ideas in that it shows that the dreaming parts of the brain are closely related to motivational systems.

The *system preconscious*, the middle layer of the mind, was thought to act to censor the unacceptable, threatening, or abhorrent wishes. The forbidden wishes were only allowed access to consciousness if they were so distorted that their unconscious origins could not be detected. The experimental studies of perceptual defense support Freud's suggestion that the motive for censorship is perhaps the avoidance of displeasure associated with the conflictual idea. These studies have demonstrated that some people have a higher perceptual threshold for distressing stimuli than neutral words. It is assumed that subjects in these studies perceive and evaluate the word preconsciously and block it from entering consciousness.

The *system conscious*, the uppermost layer of the mind, consisted of reality-oriented perceptions, thought sequences, or problem-solving analysis dominated by secondary process thinking. The system conscious was assumed to be organized by logic and reason and was primarily concerned with external reality—safety from danger and civilized behavior.

In the topographic model, the mind conflicts with the repressed forces and the repressing forces, and the symptom is viewed as essentially a compromise between conflicting forces. Repressive ideas reach consciousness under specific conditions, such as when the repressive barrier is overpowered (as in psychoneurotic symptom formation), relaxed (as in dream states), or fooled (as in jokes). Furthermore, traumatic experience occurs when the conscious part of the mind is overwhelmed by pressure to gratify unconscious wishes, followed by intolerable feelings of rejection or punishment. The shift in emphasis on fantasy over reality led Freud to explain all human behavior in terms of the failure of the child's mind to deal adequately with the pressures of biologic drives. Freud discovered during his clinical work that repression of a childhood memory could occur if energy were withdrawn from it and, especially if verbal energy were removed. This repressive force or *countercathexis* manifests itself in psychoanalytic treatment as resistance to remembering. When the words were reconnected to the forgotten memory traits (as during psychoanalytic treatment), it became recathected and could thus reach consciousness once more.

Psychosexual Development. The shift in emphasis from reality to inner motivations and fantasy marked the beginning of psychoanalysis. Psychoanalysis took on a new and highly significant dimension to distinguish psychic reality and fantasy from actual external events. This shift in direction inevitably led to the emergence of a dynamic theory of infantile sexuality in which the child's psychosexual life played a significant and dominant role. According to the theory, sexual instincts seek expression throughout life, which the individual tries to master to conform to society's demands. These biologic tension states are represented mentally in terms of wishes and are directed towards external objects for their satisfaction.

The earliest manifestations of infantile sexuality arose with bodily functions regarded as basically nonsexual, such as feeding and developing bowel and bladder control. However, Freud saw that these functions involved degrees of sensual pleasure, which he interpreted as forms of psychosexual stimulation. Freud used the term *sexual* in an extended sense to mean physically pleasurable. He identified a succession of three developmental phases in developing infantile urges, each of which was thought to build on and subsume accomplishments of the preceding phases—namely, the *oral*, *anal*, and *phallic phases*. The oral phase occupied the first 12 to 18 months of the infant's life; next came the anal phase, lasting until about 3 years of age; finally, the phallic phase, from approximately 3 to 5 years of age. Later, the *latency phase,* from ages 6 to puberty, and the *genital phase*, from puberty onwards, were added to complete the picture.

Freud postulated that phallic erotic activity was essentially a preliminary stage for adult genital activity in boys. In contrast to the male, whose principal sexual organ remained the penis throughout psychosexual development, the female had two leading erotogenic zones, the clitoris, and the vagina. Freud felt that the clitoris was preeminent during the infantile pregenital period but that after puberty, erotic primacy was transposed to the vagina. Recent sexual investigations have cast doubt on a supposed transition from clitoral to vaginal primacy.

Karl Abraham modified and refined Freud's basic schema of the psychosexual stages. He further subdivided the phases of libido development, dividing the oral period into a sucking and biting phase and the anal phase into a destructive–expulsive (anal sadistic) and a mastering–retaining (anal erotic) phase. Finally, he hypothesized that the phallic period consisted of an earlier phase of partial genital love, which was designated as the true phallic phase, and a later, more mature genital phase. For each of the stages of psychosexual development, Freud delineated specific erotogenic zones that gave rise to erotic gratification.

The theory has evolved based on direct empirical and experimental observations of children in child analysis and developmental studies as opposed to relying on the reconstruction of childhood memories in adult analysis. It now focuses less on libidinal phase specificity with a progression of libidinal stages from oral to genital in a prescribed order, and places greater emphasis on the complex integration of multiple developmental influences. These include maturational factors, temperamental dispositions, object relations involvement, affective and cognitive development, language acquisition and related phenomena. Accordingly, there is a greater inclination to view libidinal stages as more loosely organized, intermingled, and not necessarily rigidly sequential.

The topographic theory assumed the existence of *psychological energies* that originated in instinctual drives. This assumption was derived from the observation that recall of traumatic experiences and their accompanying affects resulted in the disappearance of symptoms and anxiety. This suggested, therefore, that a displaceable and transformable quantity of energy was involved in the psychological processes responsible for symptom formation. Freud originally assumed that this quantity was equivalent to the affect, which became dammed up or strangulated when it was not appropriately expressed and, thus, was transformed into anxiety or conversion symptoms. After he had developed his notion of instinctual drives, this quantitative factor was conceived of as drive energy *(cathexis*). The assumption of psychic energies served Freud as a vital heuristic metaphor. The usefulness of the metaphor and its necessity as a basic assumption of analytic theory has subsequently been questioned and found wanting. Refocusing these observations in motivational terms loses nothing in terms of explanatory potential.

Freud’s deepening appreciation of the unconscious dimension of these processes led him to view the ego as, in some part unconscious, one of the reasons for his later formulation of the structural theory in 1923.

Structural Model

Freud gradually realized the limits of the topographic model. The repeated encounters of resistance in his patients, difficulty accessing the defenses responsible for resistance, and feelings of guilt in his patients led him to conclude that the mechanism of repression was itself unconscious. These observations made clear to Freud that the ego has both conscious and unconscious components. Freud rethought his topographic model and conceived of the structural model of the mind, or the *tripartite theory* as it is often called.

Freud first introduced the structural model of the mind in *The Ego and the Id* (1923). The structural model was composed of three distinct entities or organizations within the psychic apparatus—the *id*, the *ego*, and the *superego*. Freud conceived of the id as a completely unconscious, unorganized, primordial reservoir of energy derived from the sexual and aggressive instincts and under the domination of the pleasure principle and primary process. However, id was not synonymous with the unconscious because certain functions of the ego, specifically certain defenses against unconscious instinctual pressures, were also unconscious; and for the most part, the superego also operated on an unconscious level.

In contrast to his concept of the id, Freud conceived of the ego as a coherent structure, having an organized, problem-solving capacity, whose task was to mediate between the competing demands of the id, superego, and the external reality. The ego was partly conscious but largely unconscious. The conscious part of the ego has the capacity for sophisticated psychological processes to deal with the external reality. The unconscious part of the ego regulated pressure and demands of the id and the superego by the mechanisms of defense that operate unconsciously.

The third structural component of the psychic apparatus, the superego, contained the internalized moral values, ideals, prohibitions, and standards of the childhood parental authority figures. In Freud’s view, the superego was the source of conscience and guilt. It was concerned with the ideals and morals based on unconscious learning from parents and hence society. The superego was partly conscious but largely unconscious.

The structural model assumed that most psychological processes could function outside of awareness. Freud’s view of mental processes as largely unconscious has been validated and supported by cognitive and experimental psychology. Freud believed that the ego develops out of modifications of the id, resulting from the demands and limits of the external world. The ego appropriates energies of the id to manage the pressures of the external reality. His observation that repression and resistance, both associated with the ego, could be unconscious, pointed to the need for an expanded concept of the ego. The ego was considered an organization retaining a close relationship to consciousness and external reality and yet performing a variety of unconscious operations in relation to drives and their regulation. With a broadened scope for the ego, consciousness was redefined as a mental quality that, although exclusive to the ego, constitutes only one of its qualities or functional aspects, rather than a separate mental system itself as in the topographic model. The ego controls the apparatuses of motility and perception, contact with reality, and, through defense mechanisms, inhibition, and control of primary instinctual drives.

While the ego developed out of frustrated id wishes, the superego developed out of defense against the id wishes. In the Oedipal period, the child wishes to possess the parent. Each must, however, contend with a powerful rival, the other parent. The frustration of the child’s positive Oedipal wishes by this parent evokes intense hostility, which finds expression not only in overt antagonistic behavior but also in thoughts of killing the parent who stands in the way, along with any brothers or sisters who may also compete for the love of the desired parent. Quite understandably, this hostility on the part of the child is unacceptable to parents and, in fact, eventually becomes unacceptable to the child as well. The moral objection to the id wishes form the basis of the superego. The theory contends the child’s sexual explorations and masturbatory activities may themselves meet with parental disfavor, which may even be underscored by real or implied threats of castration. Consequently, the child turns away from the Oedipal situation and its emotional involvements and enters the latency period of psychosexual development and renounces the sexual impulses of the infantile phase. It was this effort of renunciation that gave the superego its prohibiting character. However, because the superego evolved due to the repression of instinctual desires, it had a closer relation to the id than the ego itself. Its origins were more internal; the ego originated to a greater extent in response to the external world and was its internal representative.

Throughout the latency period and thereafter, the child (and later the adult) continues to build on these early identifications through contact with teachers, heroic figures, and admired persons, who form the sources of the child's moral standards, values, and ultimate aspirations and ideals. The child's conflicts with parents continue but largely internally, between the ego and superego. In other words, the child's superego internalizes the parental standards, restrictions, commands, and punishments. The superego becomes the judge and guide of behavior which operates from within, even in the absence of the parents.

EGO PSYCHOLOGY

Freud's ego was conceived as a structural entity, a coherent organization of mental processes and functions, primarily organized around the Perception–Consciousness System, which also included structures responsible for resistance and unconscious defense. However, the ego was viewed as relatively passive and weak. Its functioning was still a result of mediating the pressures deriving from the id, superego, and external reality. The ego was the helpless rider on the id's horse, more or less obliged to go where the id wished to go. The assumption remained that the ego was dependent on forces of the id and somehow genetically derived and differentiated out of the id. Freud had yet to recognize any actual development of the ego comparable to the phases of libidinal development.

However, Freud's conception of ego as a powerful regulatory force responsible for integrating and controlling behavioral responses, and the concern with the adaptive function of the ego, even though rudimentary and limited to the ego's capacity to avoid danger, provided the foundation for the refinement and advancement of ego psychology. The systematization of ego psychology stemmed from the collective works of Anna Freud, Heinz Hartmann, David Rapaport, and Charles Brenner, to name but a few giants of the ego psychology movement.

Ego Functions

Ego psychologists viewed ego as the preeminent psychic agency, as important as the drives, and studied and theorized the role of ego and its various functions as individuals adapt to their physical and social environment or modify those environments to make them more compatible with personal wishes and needs. The ego was still a subsystem of the personality and not synonymous with the self, the personality, or the character. The ego comprised a class of functions that mediated between instincts and the outside world and we share some of the important functions here.

- Ego *mediates the relation with reality*. The sense of reality originates with the development of the ego. The ability to distinguish internal reality (wishes and fears) and actual reality (events in the real world) depends first on the *primary autonomous functions* of the ego, such as memory and perception. Because of the fundamental importance of *reality testing* for "negotiating" with the outside world, its impairment is associated with a severe mental disorder.
- Ego *makes the judgment* about what is "reasonable" or "appropriate" course of action. It considers id wishes, as well as social expectations and reality considerations to arrive at sound judgment. The capacity for judgment works in tandem with reality testing.
- Ego *controls and regulates instinctual drives*. The capacity to delay the immediate discharge of urgent wishes and impulses helps the ego mediate between the id and the outside world.

Modulation of impulses involves judgment. Both too much control and too little control over impulses is problematic.

- Ego *regulates affect* by keeping out of awareness painful or unacceptable feelings, or by modulating the expression of feelings. Ego matches the feelings with the social and cultural norms to make emotional expression congruent.
- Ego *helps create mutually satisfying relationships*. The evolution in the child's capacity for relationships with others, progressing from initial relations with maternal and other caretaking figures to social relationships within the family and then to relationships within the larger community, is related to this capacity.
- Ego *mobilizes defenses* to bring instinctual demands into conformity with demands of external reality. Defenses operate unconsciously, in response to danger signals like, threatening instinctual motivations and affects. Defenses are dynamically motivated and reversible. They could be functionally adaptive as well as pathologic.
- Ego *helps maintain a steady and reasonable level positive self-regar*d by regulating negative and positive feeling states that may dysregulate *self-esteem*.
- Ego *masters challenges of each successive psychosexual stage* (oral, anal, phallic, genital) and thereby becomes more effective in organizing and synthesizing mental processes.
- *Adaptation to reality* is closely allied to the concept of mastery, both in respect to instincts and external tasks. The function of adaptation to reality is closely related to the defensive functions of the ego.
- Ego's *synthetic function* is concerned with the overall organization and functioning of the ego in the self-system. It unites, organizes, and binds together various drives, motives, tendencies, and functions within the personality, enabling the individual to think, feel, and act in an organized and directed manner. As part of its synthetic function ego must enlist the cooperation of other ego and nonego functions in its operation. Although the *synthetic function* subserves adaptive functioning in the self, it may also bring together various forces that, although

not wholly adaptive, are an optimal solution for the individual in a particular state at a given moment.

- Clinical example: Hysterical conversion combines a forbidden wish and the punishment for it into a physical symptom. On examination, the symptom often turns out to be the only possible compromise under the circumstances.

Ego Development

In addition to the maturation of relatively autonomous ego functions, the ego is built upon the basis of processes by which aspects of the external world are acquired and become part of the ego. These processes where the internal world is built, and the structure is consolidated within the self are called *internalization*. Forms of internalization—*incorporation, introjection,* and *identification*—are variously connected with the development of the ego.

Incorporation was initially conceived of as an instinctual activity derived from and based developmentally on the oral phase and was considered as a genetic precursor of identification. Incorporation as an internalization mechanism involves a primitive oral wish for union with the object. The union is total and global. The object loses all distinction and independent function and is completely assumed into the person's inner world. Incorporation thus comes into play in relatively more infantile or regressive conditions in which the sense of distinction of the object as separate is lost.

Introjection is perhaps the most central process in developing the structural apparatus involving ego and superego. Freud originally described introjection in *Mourning and Melancholia* (1917) as a process of narcissistic identification in which the lost object is introjected and thus retained as a part of the internal structure of the psyche. Freud later applied this mechanism to the genesis of the superego, making introjection the primary internalizing mechanism by which parental *imagos* were internalized at the close of the Oedipal phase. Through introjection, the child tries to retain gratifications derived from object relationships, at least in fantasy. By this mechanism, qualities of the gratifying relationship are internalized and re-established as part of the self's organization. In doing so, the child retains connection with the object, which serves both adaptive and defensive functions. Freud referred to this internalized product as a *precipitate of abandoned object cathexis.* However, because of the degree of residual object-connection, introjects are not fully integrated into the structuring of ego and superego; they retain a quasi-independence and inner presence. They have been aptly described in Kleinian terms as *internal objects*.

Identification has often been confused with introjection, partially because Freud treated the two processes as overlapping and somewhat interchangeable. Identification is an active structuralizing process within the self, by which the self-constructs the inner constituents of regulatory control. What constitutes the model of identification can vary considerably and can include introjects, structural aspects of real objects, or even regulatory components of group structures and group cultures. The identification process is specifically an intrasystemic structuralizing activity, attributed to the ego functions of the self and related to its synthetic function, affecting structural integration in all parts of the psychic apparatus, including ego and superego. By identification, the character of these structures is internally altered, such that their qualities can be regarded as authentic aspects of the self that effectively modifies aspects of autonomous self-functioning.

Heinz Hartmann's Ego Psychology

Hartmann's ego psychology advanced Freud's structural theory by pointing out that some of the functions of the ego develop autonomously of the id. He referred to these ego mechanisms as apparatuses of *primary autonomy*. He postulated that the ego and id originate from a common matrix, the so-called undifferentiated phase, in which the ego's precursors are inborn apparatuses of primary autonomy. These apparatuses are rudimentary, present at birth, and develop outside the area of conflict with the id. Hartmann referred to this as a *conflict-free zone* of ego functioning. He included perception, intuition, comprehension, thinking, language, certain phases of motor development, learning, and intelligence among the functions in this *conflict-free sphere*.

With the introduction of the *primary autonomous functions*, Hartmann provided an independent genetic derivation for at least part of the ego, thus establishing it as an independent realm of psychic organization and functioning that was not entirely dependent on and derived from the instincts. This was a formulation of significant importance because it laid the foundations for the emerging doctrine of ego autonomy and meant that the analysis of ego development would have to consider an entirely new set of variables quite separate from those involved in instinctual development.

Over time it became increasingly clear that each of the autonomous functions of the ego could become involved in conflict secondarily during development and usually did. For example, aggressive, competitive impulses could intrude on the impulse to learn, and evoke inhibitory defensive reactions on the part of the ego, thus interfering with the conflict-free operation of these functions. Hartmann also recognized that ego structures and functions, arising in conflict, could change function to become relatively autonomous from drives. He observed that the conflict-free sphere could be enlarged, and other ego functions could be withdrawn from the domination of drive influences. This was Hartmann’s concept of *secondary autonomy*. A mechanism that may arise initially in the service of defense against instinctual drives may, in time, become an independent structure, such that the drive impulse merely triggers the automatized apparatus. Thus, the apparatus may serve other functions than the original defensive function, such as adaptation or synthesis. Hartmann referred to this removal of specific mechanisms from drive influences and becoming relatively autonomous as a change of function. This view of adult behavior as having different functions, likely independent of their instinctual origins, continues to be relevant today. Hartmann’s treatment of adaptation brought the adaptational point of view into focus and was generally accepted as one of the basic metapsychological assumptions of psychoanalytic theory.

Another crucial aspect of Hartmann’s ego psychology is the importance of reality, in its broadest and most profound meanings, as a significant dimension of psychoanalytic thinking. This is a direct extrapolation of Hartmann’s thinking about adaptation. The adaptive functioning of the organism has directly to do with fitting in with the requirements of external reality and adaptively interacting with the environment, not only the inanimate but also the personal and social environment. Hartmann and his colleagues introduced the concept of *average expectable environment* which recognized the importance of actual parents and thereby the influence of the environment on the development. Along with affirming the importance of the relation between the individual and their environment, ego psychology, following Hartmann’ distinction between self and other, furthered the interest in the self in so far as relations with the outside world occur between self and other. The psychoanalytic interest in self was expanded and advanced by Heinz Kohut’s and other more structurally oriented views of the self.

Anna Freud’s Ego Psychology

Like Hartmann, Anna Freud too emphasized the importance of analyzing the ego. She developed a theory of child development which was carried further by her colleagues like Erik Erikson, Edith Jacobson, and Margaret Mahler. With her interest in child analysis, she emphasized the importance of analyzing the issues that arise in a child. In the absence of conflict, id, ego, and superego work in harmony and are hard to distinguish. However, conflict generates anxiety, which acts as a signal for the defensive function of the ego and brings forth the imperatives of id and superego. Anna Freud and her group worked to list and categorize these defenses. Her efforts opened the way to a more systematic and comprehensive study of ego defenses. In her classic monograph, *The Ego and the Mechanisms of Defense* (1936), she maintained that everyone, whether normal or neurotic, uses a characteristic repertoire of *defense mechanisms*, but to varying degrees. Based on her extensive clinical studies of children, the primacy of drives at various developmental stages evoked anxiety in the ego. This anxiety, in turn, produced a variety of defenses. Concerning adults, her psychoanalytic investigations led her to conclude that although resistance was an obstacle to progress in treatment, to the extent that it impeded the emergence of unconscious material, it also constituted a valuable source of information concerning the ego's defensive operations.

Defenses emerge early in development to help the ego mediate pressures of the id and the requirements and strictures of outside reality. At each phase of libidinal development, associated drive components evoke characteristic ego defenses. For example, introjection, denial, and projection are defense mechanisms associated with oral-incorporative or oral-sadistic impulses, whereas reaction formations, such as shame and disgust, usually develop with anal impulses and pleasures. Defense mechanisms from earlier phases of development persist side by side with those of later periods. When defenses associated with the pregenital phase of development tend to predominate in adult life over more mature mechanisms, such as sublimation and repression, the personality retains an infantile cast.

The defensive forms of ego functioning can be categorized in various ways. Defenses may be classified developmentally by the libidinal phase in which they arise or are associated. Denial, projection, and distortion are assigned to the oral stage of development and the correlative narcissistic stage of object relationships. However, defenses, such as magical thinking and regression, cannot be categorized in this way. Moreover, specific basic developmental processes, such as introjection and projection, may also serve defensive functions under certain specifiable conditions. The defenses have also been classified based on their commonly associated form of psychopathology. The obsessional defenses include isolation, rationalization, intellectualization, and denial. However, defensive operations are not limited to pathologic conditions. Finally, the defenses have been classified as to whether they are simple mechanisms or complex, in which a single defense would involve a combination or composite of simple mechanisms.

Table 6.1–1 gives a brief classification and description of some of the basic defense mechanisms most frequently employed and most thoroughly investigated by psychoanalysts.

Table 6.1–1.
Classification of Defense Mechanisms

Narcissistic-Psychotic Defenses

These defenses are usually found as part of a psychotic process, but may also occur in young children and adult dreams or fantasies. They share the common note of avoiding, negating, or distorting reality.

Projection	Perceiving and reacting to unacceptable inner impulses and their derivatives as though they were outside the self. On a psychotic level, this takes the form of frank delusions about external reality, usually persecutory, includes both perception of one’s own feelings in another, with subsequent acting on the perception (psychotic paranoid delusions). Impulses may derive from id or superego (hallucinated recriminations).
Denial	Psychotic denial of external reality, unlike repression, affects perception of external reality more than perception of internal reality. Seeing, but refusing to acknowledge what one sees, or hearing, and negating what is actually heard, are examples of denial and exemplify the close relationship of denial to sensory experience. Not all denial, however, is necessarily psychotic. Like projection, denial may function in the service of more neurotic or even adaptive objectives. Denial avoids becoming aware of some painful aspect of reality. At the psychotic level, the denied reality may be replaced by a fantasy or delusion.
Distortion	Grossly reshaping the experience of external reality to suit inner needs, including unrealistic megalomanic beliefs, hallucinations, wish-fulfilling delusions, and employing sustained

	feelings of delusional grandiosity, superiority, or entitlement.

Immature Defenses

These mechanisms are fairly common in preadolescent years and in adult character disorders. They are often mobilized by anxieties related to intimacy or its loss. Although they are regarded as socially awkward and undesirable, they often moderate with improvement in interpersonal relationships or with increased personal maturity.

Acting out	The direct expression of an unconscious wish or impulse in action to avoid being conscious of the accompanying affect. The unconscious fantasy, involving objects, is lived out and impulsively enacted in behavior, thus gratifying the impulse more than the prohibition against it. On a chronic level, acting out involves giving in to impulses to avoid the tension that would result from postponement of their expression.
Blocking	An inhibition, usually temporary in nature, of affects especially, but possibly also thinking and impulses. It is close to repression in its effects, but has a component of tension arising from the inhibition of the impulse, affect, or thought.
Hypochondriasis	Transformation of reproach toward others arising from bereavement, loneliness, or unacceptable aggressive impulses, into self-reproach in the form of somatic complaints of pain, illness, and so forth. Real illness may also be overemphasized or exaggerated for its evasive and regressive possibilities. Thus, responsibility may be avoided, guilt may be circumvented, and instinctual impulses may be warded off.
Introjection	In addition to the developmental functions of the process of introjection, it also can serve specific

	defensive functions. The introjection of a loved object involves the internalization of characteristics of the object with the goal of ensuring closeness to and constant presence of the object. Anxiety consequent to separation or tension arising out of ambivalence toward the object is thus diminished. If the object is lost, introjection nullifies or negates the loss by taking on characteristics of the object, thus in a sense internally preserving the object. Even if the object is not lost, the internalization usually involves a shift of cathexis reflecting a significant alteration in the object relationship. Introjection of a feared object serves to avoid anxiety through internalizing the aggressive characteristic of the object, and thereby putting the aggression under one's own control. The aggression is no longer felt as coming from outside, but is taken within and utilized defensively, thus turning the subject's weak, passive position into an active, strong one. The classic example is "identification with the aggressor." Introjection can also take place out of a sense of guilt in which the self-punishing introject is attributable to the hostile–destructive component of an ambivalent tie to an object. Thus, the self-punitive qualities of the object are taken over and established within one's self as a symptom or character trait, which effectively represents both the destruction and the preservation of the object. This is also called identification with the victim.
Passive–aggressive behavior	Aggression toward an object expressed indirectly and ineffectively through passivity, masochism, and turning against the self.

Projection	On a nonpsychotic level, projection involves attributing one’s own unacknowledged feelings to others; it includes severe prejudice, rejection of intimacy through suspiciousness, hypervigilance to external danger, and injustice collecting. Projection operates correlatively to introjection, such that the material of the projection derives from the internalized but usually unconscious configuration of the subject’s introjects. At higher levels of function, projection may take the form of misattributing or misinterpreting motives, attitudes, feelings, or intentions of others.
Regression	A return to a previous stage of development or functioning to avoid the anxieties or hostilities involved in later stages. A return to earlier points of fixation embodying modes of behavior previously given up. This is often the result of a disruption of equilibrium at a later phase of development. This reflects a basic tendency to achieve instinctual gratification or to escape instinctual tension by returning to earlier modes and levels of gratification when later and more differentiated modes fail or involve intolerable conflict.
Schizoid fantasy	The tendency to use fantasy and to indulge in autistic retreat for the purpose of conflict resolution and gratification.
Somatization	The defensive conversion of psychic derivatives into bodily symptoms; tendency to react with somatic rather than psychic manifestations. Infantile somatic responses are replaced by thought and affect during development (desomatization); regression to earlier somatic forms or response (resomatization) may result

	from unresolved conflicts and may play an important role in psychophysiologic and psychosomatic reactions.

Neurotic Defenses

These are common in apparently normal and healthy individuals as well as in neurotic disorders. They function usually in the alleviation of distressing affects and may be expressed in neurotic forms of behavior. Depending on circumstances, they can also have an adaptive or socially acceptable aspect.

Controlling	The excessive attempt to manage or regulate events or objects in the environment in the interest of minimizing anxiety and solving internal conflicts.
Displacement	Involves a purposeful, unconscious shifting of impulses and/or affective investment from one object to another in the interest of solving a conflict. Although the object is changed, the instinctual nature of the impulse and its aim remain unchanged.
Dissociation	A temporary but drastic modification of character or sense of personal identity to avoid emotional distress; it includes fugue states and hysterical conversion reactions.
Externalization	A general term, correlative to internalization, referring to the tendency to perceive in the external world and in external objects components of one’s own personality, including instinctual impulses, conflicts, moods, attitudes, and styles of thinking. It is a more general term than projection, which is defined by its derivation from and correlation with specific introjects.
Inhibition	The unconsciously determined limitation or

	renunciation of specific ego functions, singly or in combination, to avoid anxiety arising out of conflict with instinctual impulses, superego, or environmental forces or figures.
Intellectualization	The control of affects and impulses by way of thinking about them instead of experiencing them. It is a systematic excess of thinking, deprived of its affect, to defend against anxiety caused by unacceptable impulses.
Isolation	The intrapsychic splitting or separation of affect from content resulting in repression of either idea or affect or the displacement of affect to a different or substitute content.
Rationalization	A justification of attitudes, beliefs, or behavior that might otherwise be unacceptable by an incorrect application of justifying reasons or the invention of a convincing fallacy.
Reaction formation	The management of unacceptable impulses by permitting expression of the impulse in antithetical form. This is equivalently an expression of the impulse in the negative. Where instinctual conflict is persistent, reaction formation can become a character trait on a permanent basis, usually as an aspect of obsessional character.
Repression	Consists of the expelling and withholding from conscious awareness of an idea or feeling. It may operate either by excluding from awareness what was once experienced on a conscious level (secondary repression), or it may curb ideas and feelings before they have reached consciousness (primary repression). The “forgetting” associated with repression is unique in that it is often accompanied by highly

	symbolic behavior, which suggests that the repressed is not really forgotten. The important discrimination between repression and the more general concept of defense has been discussed.
Sexualization	The endowing of an object or function with sexual significance that it did not previously have, or possesses to a lesser degree, to ward off anxieties connected with prohibited impulses.

Mature Defenses

These mechanisms are healthy and adaptive throughout the life cycle. They are socially adaptive and useful in the integration of personal needs and motives, social demands, and interpersonal relations. They can underlie seemingly admirable and virtuous patterns of behavior.

Altruism	The vicarious but constructive and instinctually gratifying service to others, even to the detriment of the self. This must be distinguished from altruistic surrender, which involves a masochistic surrender of direct gratification or of instinctual needs in favor of fulfilling the needs of others to the detriment of the self, with vicarious satisfaction only being gained through introjection.
Anticipation	The realistic anticipation of or planning for future inner discomfort: Implies overly concerned planning, worrying, and anticipation of dire and dreadful possible outcomes
Asceticism	The elimination of directly pleasurable affects attributable to an experience. The moral element is implicit in setting values on specific pleasures. Asceticism is directed against all “base” pleasures perceived consciously, and gratification is derived from the renunciation.

Humor	The overt expression of feelings without personal discomfort or immobilization and without unpleasant effect on others. Humor allows one to bear, and yet focus on, what is too terrible to be borne, in contrast to wit, which always involves distraction or displacement away from the affective issue……….
Sublimation	The gratification of an impulse whose goal is retained, but whose aim or object is changed from a socially objectionable one to a socially valued one. Libidinal sublimation involves a desexualization of drive impulses and the placing of a value judgment that substitutes what is valued by the superego or society. Sublimation of aggressive impulses takes place through pleasurable games and sports. Unlike neurotic defenses, sublimation allows instincts to be channeled rather than to be dammed up or diverted. Thus, in sublimation, feelings are acknowledged, modified, and directed toward a relatively significant person or goal so that modest instinctual satisfaction results.
Suppression	The conscious or semiconscious decision to postpone attention to a conscious impulse or conflict.

Data from Vaillant GE. *Adaptation to Life*. Little Brown; 1977; Semrad E. The operation of ego defenses in object loss. In: Moriarity DM, ed. *The Loss of Loved Ones*. Charles C Thomas; 1967; Bibring GL, Dwyer TF, Huntington DS, Valenstein AA. A study of the psychological principles in pregnancy and of the earliest mother–child relationship: Methodological considerations. *Psychoanal Stud Child*. 1961;16:25.

Anna Freud’s view of drives was rooted in the structural model. She gave primacy to instinctual satisfaction over the role of the object. However, she took the theory forward because she was very interested in the role of real parents in shaping the development of the ego and the superego. Her theory of development was significantly more comprehensive and emphasized the interaction between drive and ego–superego development and the environmental determinants. She used the notion of developmental lines to explore the complexity of structural development. The concept of developmental lines offered a way to understand a child's behavior in its developmental context. The child's developmental profile was created, and developmental lines were used to understand problematic behavior in terms of developmental arrest or regression. Clinically, her formulation added the provision of *developmental help* to psychoanalytic work. Addressing both conflict and deficit to restore the path of normal development allowed for a more comprehensive view of development. Anna Freud's work foreshadowed the work of generations of developmental theorists that attended to pathogenic effects of childhood adversity. The notion of developmental lines and focus in clinical work on providing developmental help is reflected in the theory of mentalization and mentalization-based treatment.

Based on her work with children, Anna Freud proposed several categories of childhood disorders. These included a range of developmental disturbances such as regressive dependence, poorly controlled aggression, narcissism, object relatedness, and neurotic compromise formation like phobias and obsessions. She developed a model of anxiety that distinguished between fear of the external world (actual reactions of parents and external events) and fear of the internal world. She and her colleague, Dorothy Burlingham, identified four separate internal sources of anxiety—*annihilation anxiety*, *anxiety related to loss of object*, *anxiety related to loss of objects' love*, and *anxiety related to severe bodily injury or castration*. She linked these anxieties to development, specifically capacities of the ego. A less mature ego is unable to mentalize, regulate, or defend against the psychic pain. The infant research does not support the assumption of an infant's helplessness in the face of primitive anxiety.

MARGARET MAHLER'S DEVELOPMENTAL MODEL

The separation–individuation process advanced by Margaret Mahler and her associates was a significant empirically-based contribution to understanding the developmental process after Freud. Mahler's theory emphasizes the process of separation from the maternal orbit and the establishment of personal autonomy. Her theory, organized in terms of *phases of separation and individuation*, came under severe criticism by later developmentalists. In contrast, developmentalists, mainly following the inspiration of self-psychology and intersubjectivism, emphasized maternal dependence in development and the continuing dependent reliance on self-objects throughout the life cycle. However, these divergent emphases may not be exclusive insofar as mature autonomy does not rule out significant dependence in object relations, nor does mature dependence exclude the possibility of meaningful autonomy.

Autistic Phase

The first phase of Mahler's theory of development described the *autistic phase*: "During the first few weeks of extrauterine life, a stage of absolute primary narcissism, marked by the infant's lack of awareness of a mothering agent, prevails. This is the stage termed *normal autism*. It is followed by a dim awareness stage that needs satisfaction that cannot be provided by oneself but comes from somewhere outside the self." During the first month of life, the infant is not aware of the mother as a separate entity and is not aware that it cannot meet its own needs.

Symbiotic Phase

In the next stage, the *symbiotic phase*, Mahler articulated the origin of the initial differentiation of self and object, in which infants can be said to experience something outside of themselves, to which they can relate, as satisfying their inner needs. This dawning awareness of the external object is a significant state in the psychological development of children and involves not only cognitive and perceptual developments but also goes together with the organization of rudimentary infantile drives and affects concerning emerging object experiences. Mahler indicates that this awareness signals the beginning of *normal symbiosis* “in which the infant behaves and functions as though he and his mother were an omnipotent system—a dual unity within one common boundary.” Boundaries become temporarily differentiated only in the state of *affect hunger* but disappear again when the need is gratified. Consequently, the object is recognized as separate from the self only at moments of need so that, once the need is satisfied, the object ceases to exist—from the infant’s (subjective) point of view—until a need again arises. At this stage, physical need satisfaction and psychological need satisfaction are experienced as the same. It is not until later in development that these two processes separate.

Separation–Individuation

The *separation–individuation process* is divided into successive phases or periods—the *hatching* period, the *practicing* period, *rapprochement*, and the development of *object constancy*—describing the gradual separation from maternal dependency and the increasing autonomy of the child.

Hatching. During the *hatching* period, the child gradually differentiates out of the symbiotic matrix with effort. The first behavioral signs of such differentiation seem to arise at about 4 or 5 months and continue through about 9 months. During this time, the infant is more aware of the surrounding environment and is curious about these surroundings. The infant explores the primary caregiver as a separate entity and, becoming more mobile, starts to explore the world around them. What started as a very internal preoccupation now becomes external, focusing on the primary caregiver.

Practicing. As hatching and separation from the primary caregiver gradually increase, there is a move to the second or *practicing* subphase of separation–individuation. The practicing period can be usefully divided into an early period and a proper period. The early practicing phase begins with the infant's earliest ability to move physically away from the primary caregiver by locomotion: crawling, creeping, climbing, and assuming an upright sitting position. However, moving away from the safe protective orbit of the primary caregiver has its risks and uncertainties. In the early practicing phase, there is frequently a pattern of visually "checking back to mother" or even crawling or paddling back to her to touch or hold on as a form of "emotional refueling."

The attainment of free upright locomotion characterizes the practicing period proper. It is marked by three interrelated developments that contribute to the continuing process of separation and individuation. These are (1) rapid bodily differentiation from the mother (primary caregiver), (2) establishment of a specific bond with her, and (3) growth and functioning of autonomous ego apparatuses in close connection and dependence on the mothering figure.

Rapprochement. As testing of the freedom of individuation proceeds, by about the middle of the second year, the child enters the third subphase of *rapprochement*. The crisis in the rapprochement phase is mainly that of *separation anxiety*. The child's wishes and desires to be separate, autonomous, and omnipotent are tempered by increasing awareness of the need for and dependence on the mother. Ambivalence is also characteristic of the middle phase of the rapprochement subphase. Thus, the mother's availability and the reassurance of her continuing love and support become all the more critical. If this crisis is not resolved well, there will be an increase in extreme clinging or shunning behavior.

Object Constancy. As the conflicts and rapprochement crisis are gradually resolved, the child enters the final phase of separation and individuation; namely, the phase of consolidation of individuality and the beginnings of emotional *object constancy*. At this stage, there are significant developments in the structuralization and integration of the ego and definite signs of internalization of parental demands, reflecting the development of superego precursors.

Attainment of object constancy marks a transition from the stage of need-satisfying relationships to a more mature psychological involvement with objects. Object constancy implies a capacity to differentiate between objects and to maintain a meaningful relationship with one specific object, whether needs are being satisfied or not. Such object constancy also implies stability of object cathexis and specifically the capacity to maintain positive emotional attachments to a particular object in the face of frustration of needs and wishes regarding that object. This achievement also implies the capacity to tolerate ambivalent feelings toward the object and value that object for its qualities over and beyond the functions it may serve in satisfying needs and gratifying drives.

OBJECT RELATIONS THEORY

Object relations theory emerged more or less in parallel to the evolution of psychoanalytic ego psychology, but only gradually over the ensuing years have these parallel and somewhat independent courses of theoretical development converged into complementary rather than oppositional perspectives. The development of classical psychoanalytic theory through the elaboration of systemic ego psychology has led inexorably to understand better the ego's adaptive functions, particularly the close involvement between the ego and reality in its functioning and development. The most critical dimension of the problem of the relation to reality is relationships with others, namely the whole question of object relations. The integration of these complementary currents of analytic thinking provides a more comprehensive basis for thinking about the mind as it functions not only intrapsychically but interpersonally in its relation to others as essential sources of the social environment of the human person.

Object relations theory in its bare essentials contains several fundamental points that differentiate it from classical theory. First, the ego is conceived of as whole or total at birth, becoming split or losing inner unity due to early bad experiences in object relationships, particularly the mothering object. This point differs quite radically from the classical theory, according to which the ego begins as undifferentiated and unintegrated and only achieves unity through the course of development. Second, libido is regarded as a primary life drive of the psyche, the energetic source of the ego's search for relatedness with good objects, which is essential for ego growth. Third, aggression is regarded as a natural defensive reaction to frustration of the libidinal drive, rather than specifically as an independent instinct. Fourth, the structural ego pattern that emerges when the pristine ego unity is lost involves a pattern of ego splitting and the formation of internal ego–object relations.

Melanie Klein

The origin of the object relations view can best be traced from the contribution of Melanie Klein. Klein's theorizing based itself on Freud's later instinct theory, primarily on the *death instinct* as the central theoretical assumption of her metapsychology. Working primarily with very young children, she described instinctual dynamics in the first years of life. Driven by the death instinct, the child was compelled to rid him- or herself of intolerable, destructive impulses (predominantly oral) and to project them externally. The earliest recipient of these projected impulses was the mother's breast, providing need-satisfying nourishment and satiation (*good breast*) but also often depriving and failing to satisfy (*bad breast*). At this stage, the breast images are part-objects that the infant had yet to combine into a single whole object, the mother. Early frustration of oral needs, even in the first year of life, reinforced these trends so that the bad breast became a persecutory object that was hated, feared, and envied.

Experience of the bad breast and its associated persecutory anxiety formed the earliest developmental stage in Klein's theory: *The Paranoid–Schizoid position*. The bad breast withheld gratification and thus stimulated the child's primitive oral envy, provoking sadistic wishes to penetrate and destroy the mother's breasts and body. In boys, these primitive, destructive impulses gave rise to the fear of retaliation (based in part on projection) in the form of castration anxiety; in girls, the primitive envy was expressed in envy of the mother's breast during the oral developmental phase, and later was transformed into penis envy during the genital phase. Klein held that by the time of weaning, the child could recognize the mother as a whole object possessing good and bad qualities. However, the combination of good and bad qualities in a single object—previously separated into part-objects—created a dilemma: Destructive attacks on the bad object would also destroy the good and needed object. This prevented the child's unleashing aggressive impulses against the object. This idea laid the basis where aggression turns against the self rather than the object: *The Depressive Position*. The guilt associated with destructive wishes against the object was the precursor of conscience.

Klein's emphasis in the child's developmental experience fell on the processes of introjection and projection, derived from basic instinctual drives and their interactions with the critical and primary objects of the child's early experience. Projection of destructive superego elements permits accepting good introjects (internalization of good objects), thus alleviating the underlying paranoid anxiety. The projected superego elements were later reintrojected to become the agency of guilt and early forms of obsessional behavior. The Kleinian emphasis on good and bad introjects concentrated on vital relationships to objects at the earliest level of child development, and the delineation of the internal structuring of the child's inner fantasy world in terms of the vicissitudes of these introjects, or internal objects, provided the basis and the rudimentary content for an object relations view of development.

Thus, internal objects that were either good or bad and with whom the individual was involved in intrapsychic interactions and struggles, which were in many ways as real as those carried on with the real objects outside the person, comprised Klein's "inner world." Klein saw external object relations as derived from and influenced by projective content derived from the internal object relations.

Klein's observations and formulations had a tremendous impact, particularly in bringing into prominence the role of aggression in pathologic development, in making theorists of development much more aware of the early developmental precursors of later structural entities, and particularly in providing the basic rudiments and foundations for an emergent theory of object relations.

Klein has been generously criticized for her almost blind interpretation of all forms of aggressive or destructive intent as manifestations of the death instinct. Critics point to her failure to distinguish among the various kinds of intrapsychic content (lumping object representations, self-representations, internal objects, fantasies, and psychic structures of various kinds together indiscriminately and treating them in a unitary fashion). They also note her tendency to substitute theoretical inferences for observations. Finally, they criticize her marked tendency to predate the emergence of intrapsychic organizations that are generally thought by other theorists to be achieved only in later developmental stages, for example, locating the origin of the superego in the first year of life rather than in resolution of the Oedipal situation in latency.

Wilfred Bion

Bion extended and applied Klein's ideas, especially developing the ramifications of the notion of projective identification—a process, initially described by Klein, by which a subject displaces a part of the self into an object and then identifies with that object or elicits a response in the object corresponding to qualities of the projection. Bion applied this notion to a wide range of psychotic and cognitive operations. He developed the metaphor of the *container* and the *contained* to express how projective identification occurs, especially in the contexts of mother–child and analyst–patient interaction. The child–patient projects toxic or destructive contents onto the mother–analyst, who in turn absorbs, modifies, or *contains* it so that it becomes available in a more benign form for subsequent reinternalization by the child–patient, resulting in a healthier modification of the child–patient’s pathogenic introjects.

The British Independent School

Beginning in about 1931, a shift occurred, or a new trend in psychoanalytic thinking emphasized the primacy of the external environment and the influence of objects on development. It was advanced primarily by British theorists, among whom the work of Ronald Fairbairn, Michael Balint, and Donald Winnicott stand out.

Ronald Fairbairn

Fairbairn explored the problem of ego analysis and emphasized bringing personal object relations into the center of the theory. Whereas the ego in Freudian theory had been regarded as a superficial modification of the id, explicitly developed for impulse control and adaptation to the demands of reality, Fairbairn conceived the ego as the core phenomenon of the psyche. Rather than an organization of functions, he conceived it more specifically as embodying an authentic self, that is, as the dynamic center or core of the personality. Instead of basing his theory on the instinctual drives with their implied seeking of gratification, Fairbairn shifted the emphasis to the ego and saw everything in human psychology as specifically an effect of ego functioning.

This reorientation was accompanied by a parallel reformulation of the instinctual perspective. In general, the libido or instincts, rather than mechanisms for energic discharge, were regarded as essentially object seeking. Erotogenic zones were not the primary determinants of libidinal aims but, instead, served as channels mediating the primary relationships with objects, particularly with objects that had been internalized early in life under the pressure of deprivation and frustration. Ego development was characterized by a process whereby an original state of infantile dependence, based on a symbiotic union with the maternal object, was abandoned in favor of a state of adult or mature dependence based on the differentiation between self and object. Thus, Fairbairn conceptualized the developmental process as *vicissitudes of relations with objects* rather than the *vicissitudes of instinctual dynamics*.

The basis for much of Fairbairn's theorizing was his experience with schizoid patients. He contrasted the basic dilemma of the schizoid with that of the neurotic patients he felt were treated primarily by classical psychoanalysis. He developed the view that the schizoid was not primarily concerned with the control of threatening impulses toward significant objects but that the issue for this kind of patient was having an ego capable of forming object relations at all. The relationship to objects presented a difficulty, not because of dangerous instinctual impulses arising in connection with them, but because the ego itself was weak, undeveloped, infantile, and fragile. In the struggle to defend and protect this inner weakness, the schizoid's impulses became antisocial.

Michael Balint

Both Balint and Winnicott were concerned with levels of early developmental failure that were essentially pre-Oedipal. These manifest in personality disorders that are more primitive and more difficult to treat than the usual neurotic disorders and seem to involve critical aspects of the relationships with objects early in development. Correspondingly, they do not fit well with classical psychoanalytic structural theory, with its primary focus on issues of intrapsychic conflict.

Balint envisioned several layers of psychological functioning in analysis. The first is the familiar genital level, centered on triadic relationships and specifically on intrapsychic conflicts. These conflicts and the corresponding quality of relationships were usual and familiar in most analytic processes and could be treated using adult language in verbal interpretations. There was, however, a second, deeper level in which the conventional meaning of words no longer had the same impact, and interpretations were no longer perceived as meaningful by the patient. This was the level of *preverbal experience*. He referred to this level of impairment in object relations as the *basic fault.* Balint recognized that at this level of preverbal experience, any attempt to address or describe the child's experience in adult language is bound to fail. Problems arose in analysis when efforts were made to interpret events from this preverbal level in adult or secondary process terms.

Balint distinguished between forms of regression that he described as benign and malignant. *Benign regression* was more or less equivalent to the usual form of analytic regression to more primitive relationships with primary objects. Such regression was gradual, tempered, and modulated according to the patient's capacity to tolerate and productively integrate the resulting anxiety. During this regression, the analyst maintains the analytic structure and relation, and his empathic responsiveness made it possible for the patient to withstand this unstructured experience and keep the anxiety within manageable limits. At the level of the basic fault, the lost infantile objects can be mourned, and the quality of the relationship with them was open to reworking so that the patient's basic assumptions governing his or her interaction with the internal and external object world could be reformed.

During phases of benign regression to this preverbal and pregenital level of object relations in the analysis, the analyst could usually provide an adequate degree of empathic acceptance and recognition, rather than verbalized interpretations, of this level of the patient's unstructured and regressive experience, without anxiety or any need to escape or subvert this level of experience through interpretation. Balint felt that the dynamics at this level are more primitive than can be adequately expressed in terms of conflict because they derive from the basic form of dual relationship involved in early mother–child interaction, which is the basic fault.

In contrast, *malignant regression* tends to be precipitous and extreme; the ego is prematurely overwhelmed by traumatic and unmanageable anxiety. This anxiety prevented any effective reworking of fundamental disturbances in object relationships, recreating and reinforcing the basic fault rather than creating the conditions for its therapeutic revision. At an even deeper level, beyond the reach of analytic resources, there lies the area of creativity; that is, an idiosyncratic, uncommunicable, and objectless area beyond any conventional or linguistic expression.

Regression to the level of the basic fault was an entirely different and distinct phenomenon than the more usual Oedipal regressions experienced in the analysis of adult neurotics. In the benign Oedipal regression, the aim was to gratify infantile instinctual wishes. Regressing to the level of the basic fault, however, sought a basic recognition by the therapist and protective support and consent to express the inner core of creativity that lies at the heart of the patient's being and accounts for the capacity to become ill or well. Balint used the notion of primary love at this deepest level to describe the withdrawal of libido from a frustrating object in the effort to re-establish a certain inner harmony in which it becomes possible to recover the conditions of early care and tranquility. He referred to a *harmonious interpenetrating mix-up* to describe this early, almost undifferentiated interaction of the infant and environment. Balint's analogy was that of breathing air; the organism cannot exist without air, so air and the organism are seemingly inseparable, but to cut off the supply of air reveals both the organism's need for it and the distinction between air and the organism. In terms of *primary love*, as it came to bear in analysis, the patient would seek a basic form of recognition from the analyst, as he had from significant objects in the patient's early life experience.

Donald Winnicott

Winnicott particularly emphasized the importance of early interactions between mother and child as determining factors in laying down essential components of ego development. He was concerned with the earliest phases of the mother–child relationship and the importance of what he described as *good-enough mothering* for the child's psychic development. Development involved movement from an early stage of total or absolute dependence toward a more adult relative dependence and independence phase. As he saw it, the inherited native potential for growth was strongly influenced by the quality of maternal care. This potential for development is affected even from the moment of conception. Even before birth, the child becomes invested by a strong narcissistic cathexis that allows the mother to identify with the child and become empathically attuned to the child's inner needs as if the child were—and indeed is—an extension of her own self. He called this early prenatal involvement of mother and child-in-the-womb a *primary maternal preoccupation.* This set the stage for the development of a holding relationship, in which the mother becomes sensitively attuned to the infant's needs and sensitivities and is both physically and emotionally responsive to them, thus providing a physical, physiologic, and emotional ambiance, protection, and security for the dependent infant.

As the infant moves from this early stage of *absolute dependence* toward a more relative one, awareness of personal needs and the mother's existence as a caretaking object grows. The optimal relationship at this stage involves a continuation of protective holding, along with an optimal titration of gratification and frustration. As a result of this optimally attuned relationship between the patterning of infantile drives and initiatives and their harmonious fitting in with maternal sensitivities and responsiveness, there is a developing sense of reliable expectation that the infant's needs will be satisfied without the threat of excessive withdrawal of the mothering object and the threatening, overwhelming, and short-circuiting of the infant's initiatives because of excessive maternal impingements.

In normal development, this allowed for the emergence of a certain infantile omnipotence. From this position, the child gradually retreats due to *tolerable degrees of frustration* by and separateness from the maternal object. Although the mother continues her holding at this phase, she must yet allow enough separation between herself and the developing infant to permit expression of the baby's needs and initiatives that form the rudiments of an emerging sense of self. If she is too distant, too unresponsive, or not sufficiently present, anxiety arises and is accompanied by the fading of the infant's internal representations of her.

The transition from a phase of *absolute dependence* to one of *relative dependence* represents a crucial development in the capacity for object relations. It is accompanied by a critical transition from total subjectivity to objectivity in the perception of and relation to objects. The transition from subjectivity to objectivity is accomplished by developing transitional phenomena, expressed in the first instance in the emergence of transitional objects. These objects are the child's first object possessions that are perceived as separate from the emerging self—the first "not me" possessions. From the study of infant behavior, Winnicott argued that the *transitional object* was a substitute for the maternal breast, the first and most significant and substitute object in the environment to which the infant related. He regarded the transitional object as existing in an intermediate realm or space contributed to both by the external reality of the object (the mother's breast) and by the child's own subjectivity. This intermediate realm was both subjective and objective at once without being exclusively either.

Winnicott referred to this realm as the *realm of illusion,* an intermediate area of experience that embraced both inner and external reality and may be retained in areas of adult functioning, involving such imaginative capacities as creativity, religious experience, and art. In its primitive form, however, the transitional object commonly experienced in childhood development may take the form of a particular object, a blanket, a pillow, or a favorite toy or teddy bear to which the child becomes intensely attached and from which it cannot be separated without stirring up severe anxiety and distress. Attachment to this object was an immediate displacement from the mother's figure and represented an essential developmental step insofar as it allowed the child to tolerate increasing degrees of separation from the mother, using the transitional object as a substitute.

The mother participated in this intermediate transitional realm of illusion by responsiveness to the infant's need to continually create her as a good mother. In her sensitivity and responsiveness, she functions as a good-enough mother. However, her failure to provide such adequate mothering, either by excessive withdrawal or by excessive intrusion and control, may result in the child's emergence of a false self-based on compliance with the demands of the external environment. This condition reflected a developmental failure and often severe character pathologies.

When such patients were seen as adults, they were neither neurotic nor psychotic but seemed to relate to the world through a compliant shell that was not quite real to them or the analyst. They were often mistrustful without being specifically paranoid. They appeared withdrawn and disengaged and seemed able to relate only using the protective shell, which seemed obsessive and compliant but that separated and isolated them from meaningful contacts with their fellows, even as it provided their only basis for a relationship. These disturbed personality types, or *false-self adaptations*, reflected a fundamental impairment in very early object relations, particularly in the mutuality and responsiveness of very early mother–child interaction.

Infants who developed in a false self-mode have not experienced a maternal relationship's security and mutual satisfaction. Such mothers are emphatically out of contact with the child and react mainly based on their inner fantasies, narcissistic needs, or neurotic conflicts. The child's survival depends on the capacity to adapt to this pattern of the mother's response, which is often grossly out of phase with the child's needs. This establishes a pattern of gradual training in compliance with whatever the mother was capable of offering, rather than seeking out and finding what is needed and wanted. Consequently, the child's needs, instinctual impulses, wishes, and initiatives, instead of becoming a meaningful guide to satisfying growth experiences and enlarging capacities to interact meaningfully with objects, become from the very beginning threatening to the harmony of the relationship with the mother. She remains unresponsive to affective feedback from the child.

Winnicott's attempts to formulate treatment principles for such impaired patients were built on the model of good-enough mothering. This called for a capacity for holding, empathic responsiveness, and a capacity for creatively playful exchange that allowed the patient's capacities for growth to emerge and flourish. Such playful engagement and interaction between analyst and patient had a facilitating effect on expanding the patient's authentic sense of self, hidden behind an external facade of false–self-compliance.

HEINZ KOHUT'S SELF-PSYCHOLOGY

Beginning in the 1960s, a focus on self-concept was emerging, emphasizing the deepening psychoanalytic understanding of the human psyche. Self-psychology, as a separate movement within psychoanalysis, takes its origin from contributions by Heinz Kohut and his followers. Heinz Kohut discussed that the application of classical drive theory was not providing the clinical results with patients with narcissistic issues, and he began looking at treatment differently. Kohut linked the origin of the self to narcissism, viewing the self as the result of a separate line of narcissistic development that progresses through a series of archaic narcissistic structures toward establishing mature and cohesive self-organization. Kohut credited Heinz Hartmann with stimulating the development of a concept of the self in the context of structural theory. Hartmann's distinction between the ego and the self, casts the self in representational terms, as a complex representation, organized, and synthesized as an ego function.

Kohut posited that the negative connotation of narcissism was limiting conceptually and in practice. He encouraged further understanding and consideration of developmental progression and adaptive uses of narcissism. Adaptive uses of narcissism include self-esteem and self-confidence. He also highlighted that the patient with narcissistic personality structure also had assets, not only deficiencies. Kohut discussed that patients with narcissistic personality organization had a cohesive self, yet this self was less subject to disintegration and considered patients with a narcissistic personality more analyzable than those with a borderline or psychotic organization. Kohut's work led to a focus on the self, more or less exclusively, in terms of its subjective and experiential dimension and has subsequently become a significant stimulus to renewed interest in the self.

In Kohut's view of narcissistic development, the original *primary narcissism* differentiates during development, and in response to lapses in parental empathy differentiates into two archaic configurations, the *grandiose self,* and the *idealized parental imago.* The *grandiose self* involves an exaggerated and exhibitionistic image that becomes the repository for infantile perfection; the *idealized parental imago,* in contrast, transfers the previous perfection that was lost to an admired omnipotent object(s). There is a wish to remain in close union with the idealized parental imago. Normal development of the grandiose self leads to more mature forms of narcissism such as ambition, self-confidence, and pleasure in accomplishment. The idealized parental imago can be healthily integrated into the ego ideal with the mature values, ideals, and standards it represents.

Pathologic persistence of the grandiose self intensifies grandiosity, exhibitionism, shame, envy, depression, hypochondriacal concerns, and undermines self-esteem. Loss of the idealized object or the idealized object's love can result in narcissistic imbalance, leaving the individual vulnerable to depression, depletion, poor self-esteem, failure of ideals and values, and even self-fragmentation.

Kohut based his self-psychology on the need, both during development and during life, for empathic interaction with *self-objects.* The original self-object is the primary caregiver who provides an empathic response to self-object needs in the infant in the form of love, admiration, acceptance, joyful participation, warmth, and responsiveness, communicating a sense of valued and cherished existence to the child. However, Kohut contends that human beings seek objects to fulfill these basic self-object needs throughout life. Failure to fulfill such needs can result in pathologic psychic structures and behavior patterns during development and pathologic character structures during adult life.

Two other concepts discussed by Kohut are now often considered when evaluating patients. *Empathy* is something he valued, but not in a vague sentimental way, but using empathy to interpret what is happening in a person's life. Another concept he discussed is his distinction between self and identity. He wrote that the self refers to the core personality made up of various constituents in the interplay with the child's earliest self-objects. *Identity* is the point of convergence between the self developed between late adolescence and the sociocultural position of the individual. One might have a diffuse identity, but a strong sense of self, which Kohut posited could be the makeup of a psychoanalyst who is resistant to fragmentation but whose diffuse identity could allow them to empathize with many different types of people.

The current prevailing view of the self is Kohut's self psychology. Emphasis is placed on the initial and continuing dependence of the self concerning self-objects. Developmentally, the importance of empathic parental attunement is considered vital to normal psychic growth in the interest of facilitating infantile needs for nurturance, love, and narcissistic approval.

Theoretical gains of the emerging role of the self-concept:

1. The self as a theoretical construct provides a focus for formulating and understanding the complex integrations of functional processes that involve combinations of functions of the respective operational components of the self. This would have specific application to such complex activities as affects, in which all of the psychic systems seem to be in one way or other represented; complex ego–superego integrations reflected in such formations as value systems; and other complex interactions of psychic systems that involve fantasy production, drive-motor integration, or cognitive-affective processes.
2. The self-concept provides a more specific and less ambiguous frame of reference for articulating self-object interrelationships and interactions, including the complex areas of object relations and internalizations.
3. The emergence of a self-concept provides a locus in the theory for articulating the experience of the personal self, either as grasped introspectively and reflectively or experienced as the originating source of personal activity. This sense of the self-as-subject would provide a place within the theory for an account of subjectivity and subjective meaning.

Although a person's experience of themselves and sense of self is now a commonplace concept in psychoanalysis and therapy, Kohut did not gain wide acceptance of his theories during his lifetime. This has been attributed to his seeking to discard drive theory.

OTTO KERNBERG'S INTEGRATION OF OBJECT RELATIONS AND STRUCTURAL SCHOOLS

In contrast to Kohut's view, Otto Kernberg's view of narcissism is embedded in drive theory. Kernberg implied that both libido and aggression are invested in the self, thus constituting elements of narcissism. Aggression may be condensed within the structure of a defensive, pathologic grandiose self, constituting the basis of the most severe constellations of pathologic narcissism. Kohut and Kernberg disagree about the origin of this grandiose self and whether it reflects the fixation of an archaic "normal'' primitive self (Kohut's view) or a pathologic structure, clearly different from normal infantile narcissism (Kernberg's view). Kernberg's work includes his belief in applying libidinal and aggressive drives and applied it to object relations, especially under very activated affect states in early life. He theorizes that repressed drive elements are invested in object relations from a young age. Kernberg believes affect states representing these primitive drives are essential links between self and object representations and feels these affects are building blocks for the drives. He sees unconscious intrapsychic conflict as self and object constellations under the influence of a drive derivative on one side of a conflict and contradictory and opposing units of self and object representation and defensive structure on the other side.

A major contribution to the field was Kernberg's focus on *levels of personality organization* in the context of ego psychology. These levels have been called the *mature*, *neurotic*, *borderline*, and *psychotic levels of organization*. Severe psychopathology involves splitting mechanisms in the ego–id matrix to stabilize affects. Individuals at a higher level of organization, *mature personality organization*, having a relatively well-integrated ego and superego.

The superego is harsh and perfectionistic. The ego utilizes inhibitory defenses such as repression and reaction formation, thereby masking instinctual needs. The patient's ego is restricted, but their adaptation to the social world is not seriously impaired.

The person with a *neurotic level of organization* has fairly deep, stable object relationships and is capable of experiencing guilt, mourning, and a wide variety of affective responses, with only a partial inhibition of sexual drives. At neurotic level "the excessively punitive nature of the patient's superego is even stronger than that of the higher-level disorders, but the superego is less integrated." Often, neurotic individuals manage the contradictory demands of the cruel and prohibitive superego and the primitive and often idealized sense of who they want to become. There is a wish to be great, powerful, physically attractive, and also morally perfect. Thus, there can be a blurring between superego and ego. Mood swings within this level of organization are the result of the superego's difficulty in regulating the ego. Kernberg observed that although repression is still present, there are fewer inhibitory defenses at this higher level, more impulsivity and expression of unacceptable sexual and/or aggressive needs, as well as more reaction formation, intellectualization, rationalization, and undoing. Neurotically organized individuals have a capacity for stable, lasting relationships.

In the next lower level, later termed *borderline personality organization*, the patient's superego integration is minimal and the capacity for projection of primitive, sadistic superego elements is high. The individual uses projection and projective identification as defenses. The boundary between ego and superego is extremely blurred. The ego is unable to integrate experience and instead uses splitting and dissociation as defenses versus repression. The mechanism of splitting is expressed as contradictory ego states alternating with each other, and this dissociation is reinforced by the patient's use of denial and projective identification. These patients have trouble holding in mind contradictory ("good" and "bad") self and object images. Kernberg points to early aggressive drives making it difficult to integrate these concepts. Thus, their inability to integrate aggressive and libidinal drives leads to maintaining object relationships of either a need-gratifying or a threatening nature. They are unable to have empathy for others, trouble experiencing people in their entirety, and often have relationships that address an aspect of the other person.

Finally, at the lowest level, termed *psychotic level of organization*, the person lacks an integrated sense of self. The inner world is composed of the most negative and positive aspects of people who are important to them but are not integrated. And neither their experience of their inner world or their sense of self is integrated, that leads to identity diffusion. Without this coherence of self and experience the ego strength suffers and has trouble tolerating frustration, tolerating anxiety, trouble with impulse control, and difficulty using sublimation as a defense.

ATTACHMENT THEORY

Unlike most psychoanalytic theories that are principally based on the data derived from the clinical experience, the attachment theory is different in that it adds the perspective of systematic observation and empirical research to the development of psychoanalytic ideas. It is grounded in robust infant research that spans over a period of half a century. For an excellent recent review of attachment research that has contributed to the development of attachment theory, please refer to the third edited volume of *Handbook of Attachment* by June Cassidy and Phillip Shaver.

Attachment theory derives from the work of John Bowlby. In his pioneering work with maladjusted and delinquent children, who had experienced early and prolonged separation, Bowlby conceptualized that attachment constituted a central motivational force. Bowlby emphasized the survival value of attachment. He postulated that attachment to the mother was essential for the infant’s survival and had important consequences for later development and personality functioning. Influenced by ethologists like Konrad Lorenz, he proposed that attachment behaviors are part of a biobehavioral system. A biobehavioral system involves inherent motivation and cannot be reduced to another drive. Attachment behaviors enhance safety through proximity to the caregiver and cannot be reduced to the caregiver's feeding function. Bowlby's formulation differs from the object relations perspective in its view of relationship with the object as the primary motivator rather than the drive. Specifically, Bowlby emphasized the significance of caregiver availability and the consequent state of being or feeling close to the caregiver. He asserted that availability referred to the expectation based on repeated experience with the actual caregiver, which was represented as a model. He called it an *internal working model*. The emphasis on the "actual" presence or absence of the caregiver was again a departure from the psychoanalytic perspective of privileging the internal world of fantasy over the external world. Later researchers redefined the goal of attachment system from physical closeness to feeling of *security*, which extended the applicability of the concept of attachment across the lifespan. With the notion of felt security and the focus on internal representations in the infant and the caregiver the attachment theory increasingly recognizes the overlap between the external reality and the psychic reality.

Mary Ainsworth and her colleagues, in their pioneering work, developed a procedure to study Bowlby's conceptualization. In an arrangement for observing an infant's internal working model in action, known as the *Strange Situation*, she had infants briefly separate from their caregiver in an unfamiliar situation and she documented patterns of their attachment behaviors. Her findings led her to identify three different patterns of attachment behavior—*secure*, *anxious/avoidant*, and *anxious/resistant*. Secure infants readily explore in the presence of their caregiver, are anxious in the presence of a stranger, are distressed by the caregiver's absence, rapidly seek contact when caregiver returns, are easily reassured by contact with the caregiver, and return to exploring. Anxious/avoidant infants do not prefer primary caregiver over the stranger, they do not show distress when caregiver leaves, and they do not seek contact with the caregiver upon their return. Anxious/resistant infants are inhibited in their exploration even in the presence of primary caregiver, they are extremely distressed by caregiver's absence, and even though they seek contact when caregiver returns, they are difficult to soothe and struggle to return to exploration and play. Patterns of attachment behavior of *disoriented/disorganized* infants was added by Mary Main and Judith Solomon. This group of infants show undirected and confusing behavior and are understood to have experienced their caregivers as frightened or frightening. The experience of caregivers as both a source of comfort and fear leaves this group of infants in an impossible bind which is then reflected in their conflicting and disorganized attachment behavior.

Subsequent attachment theorists have studied these patterns of early infant attachment and related them to patterns of adult attachment. Using the *Adult Attachment Interview* (AAI), developed by Main and others, they documented the stability of internal working models, like introjections or internal objects, based on early attachment relations. It turned out that these patterns of infantile attachment could then be related to attachment attitudes in adults based on the results of the AAI. Thus, secure infants were found to develop secure and relatively autonomous patterns of attachment and interaction with others in adult relationships and were more likely to become more resilient, self-reliant, empathic, and confident in forming meaningful relationships. Avoidant or dismissing infants were found to be associated with an adult pattern of dismissing object relationships as important or significant, a combination of indifference and independence, and a form of self-reliance akin to counter-dependence and denial of any need for the presence or caring of others. Their investment is in maintaining aloofness and detachment in the service of defending against loss and separation. These infants were seemingly more vulnerable to adult disorders than others, for example, borderline, histrionic, and dependent personality disorders, and may be more challenging to treat in psychotherapy. Resistant or preoccupied infants later seemed to develop a somewhat preoccupied adult stance in which subjects are aware of attachment needs but come to expect that they will be inevitably disappointed, resulting in excessive dependency accompanied by disappointment and fears of loss and abandonment. Childhood experiences of past attachments were often connected with confused, angry, or fearful emotions, especially fears of abandonment. They seem invested in maintaining contact with need-satisfying objects but continually defending against the anxiety related to separation and loss. The disorganized–disoriented infantile pattern seemed to be related to an unresolved and disorganized pattern in adults, suggesting a more severe disturbance in self-object relations. These findings provide an extension and specification of an object relations approach and provide specific empirical and observational methods for a more detailed study of the development of object relations from childhood to adulthood. Attachment studies document the development of internal representations of object relationships and their stability and instability throughout development.

Peter Fonagy’s work on *reflective functioning,* the capacity to perceive and think about the intentionality of self and others, documents intergenerational transmission of attachment security and insecurity. Specifically, high levels of reflective functioning in mothers contribute significantly to their infants’ secure attachment. This capacity reflects the formation of coherent representations of the psychic world of others, especially caregivers, and of the subjects’ own internal states and is measured using the AAI.

Both attachment theorists and object relations theorists emphasize the significance of the mother’s empathic responsivity to the infant for self-development and relatedness, the importance of the mother–child involvement for personality development, and the role of the mother (caregiving context) as the catalyst for age-appropriate development.

Some object relations theorists have advanced objections to the attachment theory approach. Criticisms have focused on the attachment categories: they seem stagnant, lack developmental complexity, give little account of basic instinctual motivations and the role of unconscious fantasy, and provide little or no account of the progression in the evolution of object representations or patterns of internalization as development proceeds. Moreover, attachment theory pays little attention to the relational dynamics between mother and child, especially as the child progresses developmentally. No mention is made of the uniqueness of each mother–child relation and its modification by surrounding influences from other relationships.

Theoretical issues that would seem to call for clarification and integration might include the relation between mental representations and the internal working models of attachment theory. They seem analogous, and both theories remark that both representation and working models of self and others derive from experiences with early caretaking and become guides for the subsequent development of more mature object relations. However, they differ in the quality of epigenetic differentiation, representations following a specified developmental sequence and thus becoming more complex, symbolic, and linguistically mediated in contrast with internal working models that preserve a relatively constant character. This and other theoretical divergences would seem to provide a ripe field for theoretical revision and integration of these two relatively independent perspectives on early object relationships and their developmental course.

RELATIONAL THEORY AND INTERSUBJECTIVE APPROACH

The emergence of relational and intersubjective approaches to the nature of the analytic relationship has in many ways incorporated and extended aspects of Kohutian self psychology. Following Kohut's initiative, the relational perspective began by distinguishing between drive theories and relational theories, implying that viewing the analytic relation as a function of the ongoing interaction between analyst and analysand demanded the abandonment of drive theory. This dichotomy proved false in that one could entertain the relational view without dispensing with internal dynamics and psychic processes operating within the individual participants, both before and within the development of the analytic relation. Even a relational viewpoint, for example, cannot do without a system of intrapsychic motivation since the process of relating to another person and forming a relationship is itself motivated.

These approaches to understanding the analytic interaction employ a form of social constructionist epistemology in which transference is regarded as resulting from the interaction of analyst and patient. This constructivist view contrasts with the more objectivist view of traditional ego psychology and object relations. Thus, the analyst's attention is focused on the here-and-now interaction with the patient rather than only on the inner dynamics of the patient's mental life and experience. This introduces a shift from a one-person to a two-person psychology. Whether conscious or unconscious, the ongoing interactions between the participants become central, and transference and countertransference are regarded as mutually cocreated by both analyst and analysand.

Intersubjective theory further expands the self psychological emphasis on self-selfobject transferences and rejects consideration of the analyst's stance as neutral or observational, to now question the analyst's subjectivity, authority, and capacity to know any objective reality about the patient. Stephen Mitchell, Jessica Benjamin, Robert Stolorow, and Owen Renik, among others, proposed the concept of personality as developing within a relational matrix. It calls for a central focus on the intersubjective field within the relationship between analyst and patient. This aspect of the analytic situation is explored and interpreted to bring about personal growth in the patient. The analyst's technical neutrality and objectivity are rejected in this approach as illusory and little more than expressions of the analyst's authoritarian position. Within a self-selfobject or intersubjective relation approach, neutrality is precluded as potentially traumatizing and destructive to potential consolidation of the self. An inevitable consequence of these approaches is that they do away with the traditional notion of the unconscious and undercut any sense of transference as reflecting unconscious aspects of the patient's inner psychic life. Instead, transference is created anew in the present analytic interaction.

This approach radically departs from classical analytic views in its intersubjective guise. In the *intersubjective field*, cocreated by analyst and patient, both diagnosis and treatment are functions of the mutual interaction between them, implying that neither diagnosis nor prescribed therapy techniques have any objective validity but arise spontaneously from the workings of the intersubjective process. Any contribution from biologic determinants and constitutional factors, or for that matter from the prior history of object relationships and developmental vicissitudes, is discounted. Transference and countertransference arise in the immediacy of the intersubjective interaction. They develop in virtue of mutual here-and-now influences the participants exercise on each other, rather than from displacements or past projections. Questions have arisen about the meaning of the unconscious in this perspective and whether interactional determinants have replaced it. The emphasis on here-and-now interaction has promoted technical divergences such as the analyst's self-revelation and disclosure, even to the point of sharing countertransference elements with the patient. Preferences for spontaneity and self-expression prevail, even "throwing away the book" in the interest of escaping from any implication that the analyst has any knowledge, competence, skill, or authority that would disturb the presumed equality of the intersubjective matrix.

This approach has thus raised some significant epistemologic issues, perhaps the most telling having to do with the question of what a relation might be without a constitutive subject and object. Ordinarily, relations arise between a subject and an object, connecting them in some fashion. However, the relation itself arises from their mutual connection and interaction and has no meaning or existence without subject and object. Many intersubjective theorists address the relation as a third entity existing independently between subject and object. The properties of the analytic interaction arise within the relation separately and independently of the constituting subject and object, that is, patient and analyst.

The relational and intersubjective viewpoints bring into focus and articulate aspects of the analytic situation that have been less frequently discussed. These relational approaches' contribution deepens and expands one’s understanding of the analytic interaction.

NEUROPSYCHOANALYSIS

Another exciting and challenging branch of contemporary psychoanalytic thinking has arisen from the neuroscientific exploration of brain functions. The advent of neuroimaging and microelectronic brain recording devices has crossed a new threshold in understanding the brain’s functioning, from which significant discoveries emerge almost daily. Insofar as psychoanalysis is itself a scientific study of the functioning of the mind, these new developments thrust to the foreground issues related to how brain processes are involved in and related to mental functioning.

Neuropsychoanalysis explores the interface between neurologic knowledge and psychoanalytic models of the human mind. The work of neuroscience primarily involves mapping various processes in the function of the brain, from the molecular level to large-scale networks. With the evolution of neuropsychoanalysis, there is now a bridge between the worlds of neuroscience and psychoanalysis. Advances in technology now allow us to visualize discrete processes that we can now extrapolate onto psychoanalytic theory and practice, such as understanding the deep unconscious layers of the mind, the central role of emotions and interpersonal relations in mental life, and the importance of fantasy and mental representations. Neuroscience is rapidly expanding our understanding of the neural circuits involved with conscious and unconscious processes, motivation, emotion, self-regulation, memory, and interpersonal relations.

This field has been supported by cognitive, behavioral, and affective neuroscientists, developmental neurobiologists, neurologists, cognitive psychologists, neuropsychologists, and neuropsychoanalytic researchers. Some of the leading investigators in the field include Beatrice Beebe, Antonio Damasio, Vittorio Gallese, Eric Kandel, Joseph Ledoux, Helen Mayberg, Jaak Panksepp, Manos Tsarkis, Vilyanur Ramachandran, and Mark

Solms. Their work, in large part, attempts to bridge the gap between the fields of neuroscience and psychoanalysis. From Freud’s original psychoanalysis to today, there has been much debate about the legitimacy of psychoanalytic theory. Advances in neuroscience have “legitimized” various aspects of psychoanalytic thinking and theory. More importantly, they are deepening our understanding of a given analysand/patient/client, arguably the most crucial aspect of analytic work.

There is debate as to whether neurobehavioral discoveries affect analytic technique. For some individual analysts working in their consulting room, it does not matter, nor does it affect their work or approach to the patient in any significant way. Yet for others, neurobehavioral research, for example, has identified multiple and more or less independent forms of memory function, each subserved by different neural systems. Also, the primary distinction between explicit and implicit forms of memory has begun to have an impact on analytic technique, insofar as it brings into focus the problem that free associative and interpretive methods are appropriate for the recovery and processing of explicit forms of memory, for example, autobiographical memory, but not the implicit forms. Analysts are already working to determine what ways to engage with and what therapeutic use can be made of implicit memory systems.

However, although it may not matter which specific neural mechanisms are at work in producing mental actions and functions, it is imperative to identify such mechanisms. The significance, therefore, is less in terms of implications for clinical technique and practice at this point and considerably more in terms of the scientific status and integration of psychoanalytic theory. The critical focus in this area thus falls on the understanding of the mind–brain relation, or more broadly conceived, the mind–body relation.

Neuroscientific research makes it increasingly and abundantly clear that no action or function of the human mind does not relate directly to and correspond with a parallel process in the neural net. It is not surprising that the brain regulates and directs bodily functions: When one moves their hand, the corresponding activation of cells in the motor cortex seems unsurprising. However, when one imagines the outline of a triangle or when one adds a set of numbers, it seems surprising that parallel activity can be identified in the brain. The more complex the system the seemingly harder it is to understand for some. The neural net is vast. We have yet to discern discrete processes for complex thoughts however we are clearer on patterns of connections between the different regions of the brain. Initially, the brain was conceived of discrete areas with very discrete and singular functions, just as Freud had originally conceived of the systems of the mind as three discrete independent entities. Years of vigorous study combined with clinical observations have shown that there are very few discrete processes at play outside of the basic human functions. As we come to understand the vastness of these connections and corresponding behaviors, it can help us to determine or modulate our approach with a patient based on their unique story and experiences.

The stumbling block for many analysts is that there seems to be an inescapable gap between neuroscience on one side and psychology and psychoanalysis on the other. Neuroscience focuses on third-person data, observations, and measurements of neural processes, electrochemical transmission patterns, and the activations of neurophysiologic organization traced by multiple imaging and neural recording techniques. In contrast, analysis studies the inner psychological processes in the mind; the data are subjective, first-person in character, not available simply to external observation but only through subjective processes of introspection, recall, and association. The nature of the data and methods of acquiring the data has been perceived as different and independent. Contemporary neuroscientific studies incorporate clinical observation which is serving to bridge the gap between the channels of knowledge about the human phenomenon. Either one without the other provides no more than a limited and incomplete understanding of what is essentially a complex, integrated, and unified mind–brain entity that constitutes the reality of the human person or self.

Nevertheless, the fact remains that neuroscience currently offers a kind of evidence that was not available to previous generations, including Freud. It is as though the brain going into action in performing mental acts can almost literally be seen. The connection is no longer an inference but more akin to an observation. Current understanding of the functioning of the upper brainstem, as an example, helps to illuminate the innate nature of drives. One can argue that there is direct causality when effects follow acts. It opens the possibility that the brain is directly causing these effects, that mental actions are equivalently actions of the brain. The conclusion would have far-reaching effects on how subjective phenomena are understood. Further, the role of psychoanalysis as a scientific study of the mind would be more clearly established and confirmed. However, these questions and the possible alternatives they open are still matters of active debate and reflection.

PSYCHOANALYTIC THEORY IN PRACTICE

Psychoanalytic ideas have been inspiring psychological theories and practice since their inception. These ideas remain radical and are richer beyond comparison in describing mental functioning. The curiosity about the meaning of mental experience encouraged by psychoanalytic theories provides clinicians with an understanding of their patients that's complex, deep, and particularly useful when making sense of intense and disturbing clinical interactions.

Psychoanalytic practice provides an unparalleled window on human behavior and experience. However, it has not been easy to illustrate the translation of psychoanalytic theory into effective treatment. Psychoanalysis is not yet able to explain with precision the nature of therapeutic action. Also, it has lagged in gathering evidence to support its effectiveness. More broadly, the practice of psychoanalysis has been slow to develop, especially compared to the significant advancements in psychoanalytic theory. Of note, Freud developed his practice on a trial-and-error basis. For example, he discovered free association as he abandoned hypnosis, which he then put forward as a psychoanalytic technique. Psychoanalytic techniques discovered and proposed by psychoanalytic ancestors continue to guide the clinical work. These time-honored techniques and principles have changed little over the past century. The other issue is that the techniques don't have a one-to-one correlation with the theory. All too often one theory can be used to justify varied psychoanalytic practices and the same technique can be linked back to more than one theory. Additionally, psychoanalysts have lagged in gathering evidence to support their claims of effectiveness of psychoanalytic treatment. Although not impossible, the challenge that psychoanalysts face in this regard is twofold. One, it is both difficult and counterproductive to manualize psychoanalytic treatment, which is long term, highly subjective, and unique to the patient–analyst dyad. Two, the research methodology in current use is not up to par in its ability to capture the subjective experience that is at the core of psychoanalytic treatment.

Of Freud's two radical propositions regarding mental suffering and its treatment, the notion that *symptoms have meaning* and can be understood in terms of *unconscious beliefs and affects* has been well supported by research but there is far less evidence to support the claim that it is indeed curative to communicate the understanding of mental functioning to the patient. What effects cure and how remains a serious query for practitioners of psychoanalysis. Even though there remains a gap between psychoanalytic theory and practice, familiarity with psychoanalytic theories such as the one's reviewed in this chapter is crucial for the clinicians interested in appreciating the complexity of the clinical encounter. Moreover, the advancements in genetics and neuroscience have been strengthening psychoanalytic convictions regarding dynamic mental functioning. The recent advances in neurosciences are also leading the way forward in identifying objective indicators to support the practitioners of psychoanalysis in proving the effectiveness of their practice. The psychoanalytic technique, on the other hand, has evolved from clinical experience. All psychoanalytic practice is based on cumulative clinical wisdom supported by theory-driven framework of psychological mechanisms. Below is a brief discussion of generally agreed upon principles of psychoanalytically derived clinical practice and their compatibility with progress being made in related fields of study of mind.

Focus on the Internal World

All psychiatric disturbance involves the interaction of genetics and environmental factors. The knowledge emerging from genetic research over the last three decades, however, has led to a cultural shift in psychiatry. Instead of looking for ways to integrate the psychoanalytic insight with the neurobiologic findings the trend is towards the dominance of the biologic model of mind and psychopathology. The psychoanalytically derived clinical work challenges the equating of brain and mind and values the internal world of wishes, fears, fantasies, and dreams. The move away from reductionist either–or thinking is essential for today's psychiatrist to provide adequate patient care. The studies attempting to control the effect of genetics on development of disturbance demonstrate the considerable influence of early experience and underscore the potential danger of genetic reductionism. Contemporary genetic research in fact, shows that expression of genes is highly regulated by environmental influences. This has substantial clinical significance for psychodynamic practice. The psychodynamic focus on intrapsychic variables has much to contribute to the way gene–environment correlations and interactions may or may not be expressed in the individual patient's psychic disturbance.

Dynamic Unconscious

The hallmark of psychoanalytically oriented clinical work is the attention to dynamically unconscious mental life to account for symptoms and behaviors. Cognitive neuroscience has revealed that most of the work of the brain is nonconscious, which includes nonverbal behaviors, patterns of relatedness, procedural memory, and implicit aspects of cognitive tasks like decision making among others. The psychodynamic clinician offers uniquely significant insight into complex and often contradictory and conflicted human behavior by its focus on unconscious motivational and affective processes.

Unconscious Motivation

A key tenet of psychoanalytically oriented clinical work is the assumption of the ubiquity of *psychic conflict*. All human behavior and symptoms are compromises or adaptations to the internal and external demands. Human behavior and symptoms have multiple antecedents and varied explanations. They are the end result of conflicting and corresponding demands of several different unconscious processes involving drives, defenses, object relations, external reality, and they serve many different functions.

Early Childhood Experience

All psychodynamic formulations assume a correspondence between early childhood experiences and later psychopathology. Advances in infant research have proven beyond doubt the importance of early experiences for healthy development. Moreover, attachment researchers have documented the adverse impact of early disturbances in attachment relationships.

Mental Representation of Relationships

Psychoanalytic object relations theory emphasizes the mental representations of relationships as mediators of healthy and unhealthy behavior. The analytic or therapeutic relation can be conceived as composed of at least three coexistent components, mutually interacting, and influencing, and intermingled at all points in the analytic process—the transference and countertransference, the therapeutic alliance, and the actual relationship. Although constantly interacting to influence the patterns of interaction between analyst and patient and determining the course of the analytic process, they can be usefully distinguished in that they point to differentiable issues and aspects of the therapeutic process and call for different therapeutic responses and interventions. While transference and countertransference play an undoubtedly central—often dominant—role in the analytic process and interaction, the influences from the alliance and real relationship remain continually active and should not be ignored.

Transference. *Transference* is at the heart of psychoanalytic process and technique. Transference phenomena refers to the persistence of early patterns of mental organization in adult life. Through free association, unconscious patterns of the patient's mental organization, which may refer to events or fantasies in the patient's private experience, are brought to life and activated in the relation with the analyst. In the simplest model of transference, the analyst is gradually invested with emotions usually associated with significant figures in the past. The patient displaces or projects feelings originally directed toward these earlier objects onto the analyst, who then is perceived alternately as a friend or enemy, one who is nice or frustrates needs and punishes, one who is loved or hated, and so on, as the original objects were loved or hated. Moreover, this tendency persists, so that the patient unconsciously reenacts the past relationships with the analyst and in so doing introduces the analyst to significant figures from the past. The transference object is the lens through which the patient views the analyst, seeing him or her in the image of the transference representation.

The concept of transference has undergone considerable elaboration over time, resulting in multiple variants, broadening its connotations to include every emotional connection to the analyst, and extending the transference model to encompass the widening range of psychopathology addressed by psychoanalysis. Analysts differ regarding the degree to which emphasis is placed on the role of transference in analysis. Some insist that analysis is incomplete unless a full-blown transference neurosis is developed and ultimately resolved over the course of the analysis. Others feel that transference phenomena are to be expected, but that the development of a transference neurosis as such is neither necessary nor common. Others, especially relational and intersubjective theorists, dismiss the classic notion of transference and focus on the here-and-now interaction between analysts and analysand. In classical terms, the unresolved childhood attitudes and feelings emerge and function as displacements or fantasied projections toward the analyst, and he or she becomes for the patient a phantom composite figure representing various important persons in the patient's early environment or objects represented in his or her inner world. The past relationships are reactivated with some of their original affective vigor, thus exposing in some degree the roots of the patient's disturbance. In the relational approach, transference is thought to be cocreated by both analyst and patient, and the resulting interaction is appreciated as the emerging pattern of relatedness with the analyst within the analysis.

In psychoanalytically oriented clinical work transference represents therapeutic material to be explored and understood. Understanding transference requires exploration of mechanisms involved in their formation and their dynamic interactions. The basic mechanisms by which transferences are affected include displacement, projection, and projective identification (see Table 6.1–2).

Countertransference. Just as the patient has transference, the analyst or psychiatrist has *countertransference*. This means that the analyst unconsciously experiences the patient as someone from the past. This is usually in response to the patient's transference. The concept of countertransference has evolved dramatically since its inception. Originally countertransference was seen as the analyst's transference to the patient or the analyst's response to the patient's transference. That is, the emergence of unresolved conflicts from the analyst's unconscious affecting their view of and reaction to the patient. This early view of countertransference saw it as a hindrance to treatment and a problem for the analyst that required treatment. However, in current thinking it is seen as encompassing the total affective response of the analyst to the patient, whether conscious or unconscious. This broader definition of countertransference as the analyst's natural emotional reaction to the patient conceptualizes countertransference as the therapeutic tool that is used to attune to the patient's internal world. The emphasis is on the possible positive contributions to more effective analytic work arising from attention to and utilization of countertransference responses in an analysis. Countertransference has thus become regarded as inevitable and a possible form of communication within the analytic process, not necessarily destructive to the analytic process.

Table 6.1–2.
Transference Mechanisms

Displacement

The basic mechanism of classic transference paradigms in which an object representation or representations derived from any level or combination of levels of the subject's developmental experience are displaced to the representation of the new object, namely the analyst, in the therapeutic relationship. Displacement is usually the basic mechanism for libidinally based transferences, both positive and erotic, as well as for aggressive and especially negative transferences. By and large, displacement transferences tend to play a more dominant role in neurotic disorders, in which phallic–Oedipal (and to a lesser degree pre-Oedipal) dynamics tend to play a dominant, though not exclusive, role.

Projection

Projection is the process by which qualities or characteristics of the self, specifically the self-as-object, usually involving introjections or self-representations, are attributed to the object representation of an external object, and the subsequent interaction with the object is determined by the projected characteristics. Thus the analyst-object may be seen as sadistic, that is as possessing the sadistic character of the analysand-subject, an aspect of the subject's self that is denied or disowned by the subject. Projection tends to play a more prominent, though again not exclusive, role in formation of transferences in more primitive character disorders, but can be found in variously modified forms throughout the spectrum of neuroses. Since projections derive primarily from the configuration of introjects constituting the patient's self-as-object, the effect of projective or externalizing transferences is that the image of the therapist comes to represent part of the patient's own self-organization rather than simply an object representation as such.

Projections derived from destructive introjects can provide the basis for both negative and paranoid transference reactions. Those based on the victim-introject result in the patient relating to the therapist as a victim and him- or herself assuming a correspondingly hostile or sadistic position as a destructive aggressor or victimizer in relation to the therapist's role as victim. Then again, projection based on the aggressor-introject results in the patient relating to the therapist as an aggressor and him- or herself assuming the role of a weak, vulnerable, or masochistic position in which he or she becomes a passive and vulnerable victim of the therapist's destructive aggression. Similar patterns can take place around narcissistic issues involving introjective configurations of narcissistic superiority and inferiority. From the narcissistically superior perspective, the transference takes the form of seeing the analyst as superior, idealized, valuable, and exceptionally gifted or intelligent, while the patient retains within him- or herself the image of narcissistic inferiority, worthlessness, inadequacy, and diminished self-esteem. The opposite configuration obtains from the narcissistically inferior perspective —the analyst is then seen in the light of the projected image as inferior, inadequate, worthless, and so on, while the patient retains a view of him- or herself as superior, valued and valuable, narcissistically enhanced, even grandiose and exceptional.

However, projective dynamics in self-object transferences seem to involve more than narcissistic projections, since these forms of transference tend to draw the analyst into meeting the pathologic needs of the self. If anything is projected, it would be an infantile wished-for imago, one lacking earlier in the patient's experience, as for example an empathic and idealized parental figure. On the other hand, transitional transferences, despite their considerable overlap with self-object phenomena, tend to involve a more explicit projective element as the self-related contribution to the transitional experience.

Projective Identification

The concept of projective identification was first proposed by Melanie Klein, arguing that the projection of impulses or feelings into another person brought about an identification with that person based on attribution of undesirable dimensions of one's own qualities to that other. This attribution also served as the basis for a sense of empathy and connection with the other. On these terms, projective identification was a fantasy taking place solely in the mind of the one projecting.

Projective identification is often appealed to as a mechanism of transference, or more exactly transference–countertransference interactions. Confusion arises from the failure to clearly distinguish between projection and projective identification. The notion of projective identification added to the basic concept of projection the further notes of diffusion of ego boundaries, a loss or diminishing of self-object differentiation, and inclusion of the self as part of the object.

Later elaborations of the notion of projective identification transformed it from a one-body into a two-body phenomenon, describing interaction between two subjects, one of whom projects something onto or into the other, whereupon the other introjects or internalizes what has been projected. Instead of the projection and introjection taking place in the same subject, the projection now takes place in one and the internalization in the other. This latter usage has led to extensive extrapolation of the concept of projective identification to apply to object relations of all sorts, including transference. The emphasis in Kleinian transferences is less on the influence of the past on the present, but rather the influence of the internal world on the external in the here-and-now interaction with the analyst.

It is worth noting that there can be important clinical differences between displacement and projective transferences, especially when the latter involve projective identification. Generally, in displacement transferences, the emphasis is on the patient’s experience of the analyst object as like a previous object. The process is by and large internal with little in the way of external influences to draw the object into conformity with the image. Projective transferences have a different quality, in that part of the patient’s self is experienced as in the other. This calls for differences in therapeutic handling and interpretation. Moreover, any interpretation without substantial evidence pointing to the presence of the projected qualities within the patient’s self would be less than optimal. When projective identification is in question, the same kind of evidence is required, but in addition, the projection carries with it the effort to influence the analyst to unconsciously internalize and thus enact the role that the patient seeks to impose on him or her. This can and often does elicit some form of countertransference reaction in the analyst, resulting in a transference–countertransference interaction, which can complicate and even derail the analytic relation and process.

Understanding of one’s countertransference pull(s) is quite helpful when working with patients in analysis, psychotherapy, or pharmacotherapy. By being aware we are less likely to act on our feelings (both positive and negative) in a way that is detrimental to the patient and treatment. It can also serve as useful in terms of diagnostic understanding of patients, as well as in gaining insight into the relational difficulties the patient may encounter in their lives.

Real Relationship. Every clinical relationship is a mixture of transference phenomena and the *real relationship*. Reality pervades the analytic relationship by way of the clinician’s irreducible subjectivity. Both the analyst and analysand bring their unique personalities and characteristics to the analytic encounter. These include style of behavior and speech, mannerisms, habits, way of going about the task of managing the therapeutic situation, attitudes toward the patient as a human being, prejudices, moral and political views, personal beliefs and values, gender, racial, and sexual identity among others. These aspects of the analyst’s personality and humanity are realities that play a role in the therapeutic relationship and are entirely distinct from transference, countertransference, and the alliance. The patient is curious about, observant, and sensitive to the smallest details of the analyst’s real person and life. The same considerations concerning the patient operate from the analyst’s side. Important aspects of the reality of the patient’s person and life situation play a decisive role in the analyst’s evaluation of analyzability and continue to present themselves throughout the analysis as subjects of analytic concern, inquiry, and exploration since they contribute to and affect the patient's ongoing life and experience and his or her participation in the work of the analysis. If, for example, a patient is having marital problems, this must have significant reverberations for what happens in the analysis.

Additionally, the realities of time, place, and circumstances external to the analytic setting constantly influence the course of the analytic relationship. These include realities of the location of the analyst's office, the physical surroundings, the furniture and decorations in the room, the geographic location itself, and even how the analyst dresses; they all have their effects on the analytic situation and influence how the patient experiences the person of the analyst. The surrounding circumstances that create the context for the analytic effort—the patient's financial situation, marital status, job demands, payment arrangements, insurance, pressures pushing the patient into treatment, accidental factors like illness, family, or business obligations—are all factors extrinsic to the analysis but exercise significant influence on the analytic relationship.

Therapeutic Alliance. The *therapeutic alliance* is based on the one-to-one collaborative relationship that the patient establishes with the analyst. It encompasses aspects of the analytic frame that enable the patient and analyst to engage meaningfully and productively in the analytic process to achieve therapeutic benefit. The *working alliance* contributes to or sets the stage for the effective working together of the analyst and the analysand. The terms of the alliance are negotiated between the analyst and the patient and includes at least the following elements: empathy, trust, autonomy, continuity, commitment, responsibility, management of time and money, authority, freedom, honesty, and neutrality. All these elements are as pertinent to the role of the patient in analysis as to the analyst.

The working alliance is the permanent aspect of an analysis. It allows a split in the respective selves of both patient and analyst. The observing ego of the patient allows him or her to ally with the analyst in a working relationship. This opens the way for the patient to gradually identify positively with the analyst in the analyzing function and thus modify the pathologic defenses put up by the defensive ego against the anxiety aroused by internal danger situations. Similarly, the split in the analyst allows him or her to engage affectively and emphatically with the patient while at the same time preserving an observant, reflective, and neutral analytic stance from which he or she can understand and effectively interpret the meaning of the patient’s experience and behavior.

The maintenance of the therapeutic split and the relationship to the analyst involved in the therapeutic alliance requires a certain level of ego strength. It involves capacity for self-object differentiation, tolerance, mastery of ambivalence, and separation of fantasy from reality in the relationship. When these ego capacities are weak the alliance requires work and effort to establish, and the alliance serves as one of the objectives of the analytic work. The alliance can never be assumed or taken for granted and misalliances must be carefully looked for and attuned to, to avoid crisis or impasse in analytic work. In more severely disturbed personalities, there is a tendency to disrupt the alliance rather than create misalliances, which can destroy an analytic process and requires extreme efforts to salvage the therapy.

Maintenance of the therapeutic alliance requires that the patient differentiates between the more mature and more infantile aspects of his or her experience with the analyst. The therapeutic alliance serves a double function. On the one hand, it acts as a significant buffer to excessive regression of the ego in the analytic process; on the other hand, it serves as a fundamental aspect of the analytic situation, against which the wishes, feelings, and fantasies evoked by the transference and transference neurosis can be evaluated, measured, and interpreted. In many pathologic conditions—some character neuroses, borderline personalities, and more severe neurotic disorders—it may be challenging to maintain a clinical distinction between therapeutic alliance and the transference neurosis.

The therapeutic alliance derives from the mobilization of specific ego resources relating to the capacity for object relations and reality testing. The analyst must direct attention toward eliciting the patient's capacity to establish such a relationship that will withstand the inevitable distortions and regressive aspects of the transference and transference neurosis. Inevitably, the fundamental features of the therapeutic alliance are carefully evaluated, understood, and ultimately integrated with the analysis of the transference. When therapeutic misalliances arise, as they invariably will, they can become matters of inquiry and interpretation—more often than not, they reflect unconscious and hidden transference dynamics that otherwise have not been previously recognized or explored in the analysis. Analysts should remain alert to such misalliances in that they often provide subtle indications that something is awry in the analytic work that will both require readjustment and offer the potentiality for deeper transference exploration.

Resistance. Even the most conscientious efforts on the part of the patient to engage in the work of analysis and say everything that comes to mind are never entirely successful. No matter how willingly the patient may attempt to free associate, the signs of *resistance* are apparent throughout every analysis. The manifestations of resistance are protean.

The development of resistance in the analysis is automatic and independent of the patient's will just like the development of the transference itself. The sources of resistance are just as unconscious as the sources of transference. However, the emotional forces that give rise to resistance usually defend against or express those that produce the transference. The analysis is the recurring field of conflict between the tendencies toward transference and resistance, manifested by the involuntary inhibition of the patient's efforts to associate freely.

Resistance occurs in all phases of the analysis, but its quality and significance are different, depending on the analytic task at hand. In any case, the patient's resistance enables the analyst to evaluate and become familiar with the defensive organization of the patient's ego. In this way, the pattern of resistance offers valuable information to the analyst about the patient's basic conflicts and offers a channel by which the patient can be approached therapeutically. Of note, the use of the term resistance has been waning in contemporary theory and practice with the emerging understanding of the analytic process. There is broadening of understanding of reasons why patients resist therapeutic change. Manifestations of resistance include:

- Pausing abruptly
- Correcting oneself
- Slips of the tongue
- Stammering
- Remaining silent
- Fidgeting, for example, with a part of clothing
- Asking irrelevant questions
- Intellectualizing
- Arriving late for appointments
- Finding excuses not to keep appointments

TECHNICAL ASPECTS

Analytic technique is adapted to the idiosyncrasies of the patient's developmental capacities, needs, conflicts, compromises, and defensive constellation. It is part of the dynamic analytic process intended to induce and achieve significant internal psychic growth. A few of the more salient techniques are as follows.

Free Association

The cornerstone of the psychoanalytic technique is *free association*. As many have noted, the process of associating is not altogether free but is to a certain degree guided by the expectations of the analytic setting and the analyst's responses toward more meaningful or affectively loaded or conflictual material. The patient is encouraged to free associate as far as possible throughout the treatment. Besides providing analytic content, the primary function of free association is to help induce the necessary regression and relatively passive dependence connected with establishing and working through the transference. Thus, free association is conjoined with the other techniques that induce such regression, namely lying on the couch, not seeing the analyst, and conducting the analysis in an atmosphere of quiet reflection and restful tranquility.

The patient's free association reflects the complex influences arising from transference, the real relationship, and the therapeutic alliance. The process of free association is complex, challenging to conceptualize, and increasingly seen in the context of the relationship between analyst and patient. From a contemporary perspective much more is required of a patient than simply free associating. It is not enough for the patient to lie back and self-surrender to passive dependency within the analytic relationship without also being able to mobilize basic ego resources in the service of mastery, insight, mobilization of executive and synthetic capacities, and ultimately assumption of a less passive and more active and autonomous function within the analytic relationship. This reflects the analytic split discussed previously. There is a gradation in the mobilization of these capacities in the patient, which varies during the analytic process, optimally leading to more mature and adaptive levels as the analysis progresses, especially in the progression to the termination.

Interpretation

Interpretation was long regarded as the chief tool of the analyst in transference analysis. Current views tend to give it a more modest role. It is now conceived as part of the relational process of unconscious communication and meaning creation taking place in the clinical field. As such, it is an important technical tool among various other influences, including aspects of the analytic relationship and the quality of the analytic interaction. In the early stages of psychoanalytic therapeutic development, interpretation was used primarily to inform the patient of his or her unconscious wishes. Later, it was designed to help the patient understand the resistance to spontaneous self-awareness. In current psychoanalytic practice, the analyst's function as an interpreter is not limited to simply paraphrasing the patient's verbal reports but rather indicating what is not reported or implicit in what is reported. Consequently, analytic interpretation does not produce immediate symptomatic relief. On the contrary, even after accurate and clarifying interpretations, there may be a heightening of anxiety and emergence of further resistance.

If a correct (mutative) interpretation is given with proper timing, the patient may react immediately or after a period of emotional struggle, during which new associations are offered. These new associations often confirm the validity of previous interpretations and add significant additional data, thus disclosing motivations and experiences of the patient of which the analyst could not previously have been aware. It is not the analyst's insight into the patient's psychodynamics that produces progress in the analysis as the patient can gain their own insight, whether independently or in collaboration with the analyst. The analyst can facilitate this process by reducing unconscious resistance to self-awareness through appropriate, carefully timed interpretations. The most effective interpretation is timed to meet the patient's emerging, if hesitant and half-formed, awareness. Thus, the analyst must gauge the patient's capacity at any given moment to hear, assimilate, and integrate the content of a given interpretation.

Another critical aspect of an interpretation is that it cannot be seen in isolation from the total context of the analytic situation and the analytic process. As given by the analyst and received by the patient, an interpretation occurs within the therapeutic relationship. It may focus on elements of either transference or therapeutic alliance, or both. Giving and receiving interpretations is cloaked with meanings that influence the patient's capacity to accept and integrate interpretations and the analyst's sense of offering and providing such interpretations. Experience has shown that, at best, the therapeutic benefits produced by the analyst's explanations or unilaterally provided insights are only temporary. The most effective interpretations of lasting therapeutic value are those arrived at by the delicate dialectic arising from the mutually facilitated and growing awareness of both patient and analyst.

Interpretations are best offered in a spirit of inquiry, as hypotheses suggested for the patient's consideration and remaining open to his or her further consideration, acceptance, questioning, modification, or rejection. Interpretations, in a sense, are synonymously invitations for the patient to exercise their curiosity, reasoning, questioning, and judgment and quasiexperiments in autonomous self-reflection and analysis. Any interpretation the analyst might offer is no more than a piece of sophisticated guesswork about what the patient is thinking or meaning. Contrary to what some analysts may have thought, the analyst cannot read the patient's mind. Thus, interpretations can have little meaning or effect unless scrutinized, evaluated, and found to have application or relevance that the patient can acknowledge and accept. This cannot be achieved without the patient's active participation in the process of inquiry, discovery, and understanding of his or her unconscious thinking and motivation. In the contemporary view the quality of the relationship between analyst and patient is viewed as promoting beneficial change. The advances in neuroscience, on the other hand, emphasize the role of nonconscious, in therapeutic action. More broadly, there is a trend towards interest in and focus on how people think rather than uncovering the unconscious mental contents.

CONCLUDING REFLECTIONS

Psychoanalysis began as a revolutionary intellectual tradition and psychoanalytic ideas remain radical and relevant even as they continue to evolve and integrate the new knowledge emerging from the developments in genetic, neuroscience, and other related fields. Psychoanalytic theory is very much alive today and taking on the challenge of considering the social and cultural context, becoming more sophisticated in appreciating the gene–environment interaction, and exploring the relevance of psychoanalytic ideas and practice to the community at large. Psychoanalytic ideas continue to inspire important theories of psychological functioning and psychopathology, as well as psychological treatment although the evidence base for effectiveness of psychoanalysis itself is lagging.

Psychodynamic approach to treatment is unique in its systematic attention to the clinician's conscious and unconscious contribution to the process of treatment and evaluation. The exposure to psychoanalytic ideas prepares the psychiatrist to recognize the characterologic resistances to treatment, understand the pharmacologic noncompliance in patients along the lines of transference, countertransference, and resistance or explore the meaning of medications, thus enriching and broadening the scope of psychiatrist's practice.

6.2 Erik H. Erikson

DORIAN S. NEWTON, PH.D., AND SUDHIR KAKAR, PH.D.

“I am what survives of me.”

Erik H. Erikson was an artist, teacher, anthropologic field worker, and psychoanalyst. His legacy includes an original and authoritative theory of individual psychosocial development with cross-cultural and universal applications. Previous conceptions of personality development had been centered on infancy and childhood; Erikson's extended across the life span and was anchored in familial, societal, and historical contexts. His was a model of human experience which emphasized adaptation and growth over fixation and pathology.

A prolific writer, Erikson is best known for three major works. In *Childhood and Society*, Erikson advanced a theory of the life cycle which traced the trajectory of individual psychosocial development through the maturing ego's relations with an expanding social world. In *Young Man Luther*, Erikson reconstructed and analyzed the youthful monk's identity crisis and its creative resolution in early adulthood. *Gandhi's Truth* demonstrated the union of authentic identity and calling in a man at midlife. Through his psychological biographies of these historical figures, Erikson elucidated the interrelations between individual psychodynamics and development on the one hand and social structure and history on the other, deftly avoiding a reductionism in either a psychodynamic or sociologic direction.

Sixty-five years after the publication of *Childhood and Society*, Erikson's ideas on identity development, intimacy, and generativity continue to inspire research and engender debate.

CHILDHOOD AND ADOLESCENCE

Erik Homburger Erikson was born on June 15, 1902, in Karlsruhe, Germany, the old capital of a Lutheran principality. His father was Protestant, and his mother was Jewish. His parents, both Danish, had separated before his birth; his mother was visiting friends in Germany when the baby was born. She stayed in Karlsruhe and a few years later married her child's pediatrician, a well-to-do Jewish doctor, Theodor Homburger, in whose house young Erik grew up. During an alienated adolescence, the tall, blond boy found himself regarded as a gentile in his father's Jewish milieu and as a Jew at school. He remembered his mother as sad, bookish, and artistic; his adoptive father as professionally respected; and both as loving. The boy’s adoption by his stepfather was the formative occasion of what became a lifelong pattern of getting himself adopted by kind men. His last name remained Homburger until he was 37 when he changed it to Erikson.

Erikson attended the *Humanistische Gymnasium* in Karlsruhe, where he studied Greek, Latin, philosophy, literature, ancient history, art, and science. His primary interest was art; impatient with formal study and possessed by a restlessness he never lost, Erikson chose not to go to a university, preferring to travel about the countryside reading, drawing, and making wood carvings. Back home after a year, he tried formal art study with some success, first in Karlsruhe at the Badische Landeskunstschule and then in Munich at the Kunst-Akademie, but in neither case with decisive commitment.

This sort of wandering about was not uncommon among German youth of the period, so Erikson was permitted, as his biographer Robert Coles sagely wrote, “to go through his own years of discontent and confusion without being especially singled out and thereby forced to defend behavior often best granted the limits of its own momentum.” As Erikson confided to Coles, “ … if ever an identity crisis was central and long drawn out in somebody’s life it was so in mine.” Erikson was having what he would later term a *psychosocial moratorium*; in so doing, he was also mitigating the asperities of an *identity crisis*. At about age 21, Erikson went to live in Florence, where he continued his art studies informally. There he enjoyed the friendship of his old *Gymnasium* chum Peter Blos, a writer who later became a famous American child psychoanalyst.

BECOMING A CHILD PSYCHOANALYST

When Erikson was 25 years of age, Peter Blos invited him to become a faculty member in a progressive grammar school in Vienna, where Blos taught language and science. Erikson’s difficult transition from adolescence to early adulthood was over. The year was 1927; Sigmund Freud was 71, and his youngest child, Anna, an educator and psychoanalyst, had started a psychoanalytically enlightened school for children with an American friend named

Dorothy Burlingham. Erikson joined Blos and later recalled Blos's determination to turn him into a disciplined worker: "To make a teacher of me…the highly disciplined Peter first had to teach me to keep regular work hours, a task which was initiated every morning, no matter what time of year, by a cold shower, then the preferred shock treatment for identity confusion." At the school, "Herr Erik" taught his students art and history; together, they studied different cultures and illustrated what they learned with drawings, essays, toys, tools, and exhibits.

Before long, Erikson found himself not only a teacher of children but also an *analysand*, what is now called a *candidate*, at the Vienna Psychoanalytic Institute, in treatment with Anna Freud. Any sort of psychoanalytic approach to treating or educating children was then a radical idea, even an approach as cautious as Freud's. Both educationally and clinically, Freud's group was sufficiently deviant such that a person with Erikson's diverse identity was able to fit in. There was in 1927 a *configurational affinity* between Erikson's personal history and the history of psychoanalysis as a profession. Still, there was the worry: What was a fledgling artist without a university education to do among those high-powered theorists and intellectuals at the Vienna Psychoanalytic Institute?

Erikson recalled this epiphanic exchange with his analyst, Anna Freud: "When I declared once more that I could not see a place for my artistic inclinations in such high intellectual endeavors, she said quietly: "You might help to make them see."" Dreams had been Sigmund Freud's royal road to the unconscious; observing children's play (and later, anthropologic field studies in the role of participant-observer) would be Erikson's path to understanding the ego and its development. Looking back, Erikson thought that it was Anna Freud's "simple mandate" that enabled him to succeed in combining the artistic and the theoretical in *Childhood and Society*.

Erikson remained in Vienna for 6 years until 1933. In those years between the ages of 25 and 31, he turned his artist's eye from the observation of nature to the analysis of children; he learned about psychoanalysis by studying children's play and his own free associations as a patient, and he learned fundamental clinical skills in the supervised treatment of others. As he explained to Coles, Erikson related art to psychoanalysis in this way, “I began to perceive how important visual configurations were, how they actually preceded words and formulations: certainly dreams are visual data, and so is children’s play, not to speak of the “free associations” which often are a series of images, pure and simple–only later put into words.” Erikson trained with a Montessori group in Vienna, graduating from the Montessori teacher’s association, the Lehrerinnenverein. He studied psychoanalysis with August Aichhorn, Edward Bibring, Helene Deutsche, and Ernst Kris. He formed mentor relationships with Anna Freud and Heinz Hartmann and a more distant, admiring-inspirational relationship with Freud’s sick, aging, but still-productive father.

During his own late adulthood, Sigmund Freud had moved beyond clinical problems more narrowly conceived to problems of the ego, society, and history in works such as *Beyond the Pleasure Principle* (written at age 64), *Group Psychology and the Analysis of the Ego* (at 65), and *The Ego and the Id* (at 66); during Erikson’s years in Vienna, Freud was working on *The Future of an Illusion* (at 71) and *Civilization and Its Discontents* (at 73). Erikson seemed to identify with both Freuds, internalizing them as mentors, and they provided him with a strong, inner basis for a lifetime of psychoanalytic treatment and psychosocial research.

In 1929, Erikson met Joan Serson, a woman of mixed Canadian and American backgrounds. She had a Master’s degree in sociology, a special interest in the history and social origins of modern dance, and in psychoanalysis. They married, and Serson joined the faculty of Burlingham’s school, where she taught English, literature, and American history. Serson’s unusual combination of interests and skills—education, psychoanalysis, and sociology—coupled with her ability as a writer gave Erikson a skilled coworker for a lifetime of intellectual work. Several articles were coauthored, Joan Erikson helped with most of the others, and the endowed chair at Harvard that was named after Erikson carried both their first names.

With the birth of their sons, Kai and Jon (daughter, Sue, was to be born five years later, and their last son, Neil, was born with Down syndrome and spent most of his life institutionalized), Erikson had by 31 become a husband, a father, and a child psychoanalyst. He had come a long way from the aimless youth of his early 20s and was productively engaged in the stage of ego development that he later characterized by the polarity *intimacy versus isolation*. He continued to work on that ego stage, but changes were now required in the life that Erikson had begun to build at 25.

EMIGRATING TO AMERICA

By 1933 the Fascist menace in Europe was growing. When Erikson graduated that year from the Vienna Psychoanalytic Institute, he and his family prepared to leave. They considered repatriating to Denmark but encountered problems because Erikson had lost his Danish citizenship when he had been adopted and become a naturalized German. A serendipitous meeting between Erikson and Freud's disciple Hanns Sachs in which Sachs enthusiastically invited Erikson to come to Boston settled the matter. In 1933 the Eriksons emigrated to the United States. At 31, Erikson became Boston's first child psychoanalyst and a member of the faculty of the Harvard Medical School. He took a job as a consultant at Judge Baker Guidance Center, where he helped to diagnose and treat poor and delinquent children with emotional disorders. In Cambridge, Erikson met Margaret Mead, Gregory Bateson, Ruth Benedict, and Kurt Lewin, each of whom influenced his intellectual development in important ways.

Erikson joined a group of personality researchers working under the leadership of Henry Murray, who was the Director of the Harvard Psychological Clinic. Murray's book *Explorations in Personality: A Clinical and Experimental Study of Fifty Men of College Age* was published in 1938. It is one of the few integrative masterpieces in American psychology—experimental and biographical, psychological and sociologic, Freudian and Jungian, developmental and diagnostic—and it provided a luminous example of studying persons both in their origins and in their purposes. Murray's example proved seminal when Erikson later turned his hand to the biographical study of the world-historical figures Sigmund Freud, Martin Luther, and Mohandas Gandhi.

Listed on the title page of Murray's book, among other research associates, was "Erik Homburger." The next year, at age 37, Homburger renamed himself Erikson, retaining Homburger as his middle name. With characteristically bold creativity, Erikson solved the problem of his paternity by adopting himself.

PSYCHOANALYTIC ANTHROPOLOGY

In 1936 Erikson hit the road again, this time to the Institute of Human Relations of the Department of Psychiatry at Yale University. The interdisciplinary work of the institute further shaped Erikson's interest in cross-cultural research, and in 1938 he joined a colleague on a research expedition to the Sioux Indians in South Dakota. On the Pine Ridge reservation, he observed children, interviewed adults, and noted the impact of economic, geographical, and historical factors on child-rearing practices. Based upon this research, Erikson published his paper, "Observations on Sioux Education," in 1939.

In the same year, the peregrinating Eriksons moved to California, where he joined the faculty at the University of California at Berkeley. Erikson affiliated himself with Mount Zion Hospital and the San Francisco Psychoanalytic Institute and ultimately became a U.S. citizen. At Berkeley, Erikson continued his cross-cultural research, this time with the Yurok Indians of northern California. He also lent his research skills to the war effort in articles on submarine habitation, the interrogation of prisoners of war, and difficulties encountered by veterans in returning to civilian life.

Erikson remained at U.C. Berkeley for a decade, the longest period in one place since his preadulthood years in Karlsruhe. During that time, he became his own man, visible first in the outward signs of changing his name and later in refusing to sign the university's loyalty oath of anti-Communist purity. To Erikson, the contract was " … an empty gesture toward meeting the danger of infiltration into academic life of indoctrinators, conspirators, and spies." In 1950, following the dismissal of some of his peers for refusing to declare themselves noncommunists, Erikson resigned from his position as professor of psychology.

At Harvard, Erikson had studied “normal” students and their use of toys and dramatic scenes to enact and illustrate internal conflicts. At the Institute of Child Welfare at the University of California, Erikson continued his research and found important sex-related differences in the use of toys and play space by “normal” adolescents. As Coles noted,

> “Psychological themes—what the child says he is up to, what he can be seen doing and experiencing—are related to “spatial configurations,” namely, objects and forms that exist in a world outside the mind. The mind uses those objects or forms to express wishes, fears, and conflicts.” (Excerpted from Coles R. *Erik H. Erikson: The Growth of His Work*. Little, Brown and Company; 1970.)

In his research which had its roots in his work at Burlinghams’s experimental school, Erikson had once again combined his artistic and psychoanalytic sensibilities in the study of human behavior.

But at age 40, as Erikson was entering middle age, he was becoming more biographical and more interested in the adult years of the life cycle. Like others who manage to continue developing, he found a way to pursue his development through the strictures of exigent reality. World War II was underway, and Erikson was deeply concerned about it. After his initial narrowly framed attempts at scholarly patriotism, he began writing his first psychobiographical essays on Adolf Hitler and the psychosocial dynamics of his appeal to young Germans—“Hitler’s Imagery and German Youth” was published in 1942. It united Erikson’s interests in political science, history, and anthropology. As Coles stated, “Very little that Erikson would do for the next two decades was not in some respects foreshadowed by this paper.”

MIDLIFE TRANSITION

Childhood and Society was the creative product of Erikson’s transition to midlife. He had intended it to be a contribution to the psychiatric education of clinicians from various disciplines, but the book outgrew its author’s intentions and found its way into every corner of the academy and beyond.

Erikson began work on the book when he was 42 and largely completed work on it by 46. Published in 1950, it is at once a product of early research, a prospectus of what was to come, and an initial integration of both. In it, he presented clinical cases in which individual psychodynamics, society, and history are interwoven with a skill not seen before or since; analyses of children’s play and development in various cultures; a theoretical sketch of the entire human life cycle; pieces on the problem of identity; and biographical essays on Adolf Hitler and the Russian writer Maxim Gorky.

As in Karl Abraham’s and Freud’s psychosexual stages, most of Erikson’s stages in ego development occur in childhood and adolescence. Unlike the Abraham-Freud conception, however, Erikson’s stages are psychosocial, describing crucial steps in the maturing ego’s relations with the social world rather than a biologic unfolding of neurophysiologic capacities for excitation. Also, whereas Freud’s developmental theory falls back on itself after adolescence, Erikson’s continued with characterizations of developmental tasks during youth, middle age, and old age.

Erikson’s emphasis, like Freud’s, was both cross-cultural and universal. Erikson’s eight stages were ineluctable parts of the human life cycle, yet each person traversed them in distinct ways determined by culture, concrete circumstance, and personality. With *Childhood and Society*, Erikson became and remained an ego psychologist, shifting the traditional psychoanalytic focus on the drives to adaptation and growth. In so doing, he was furthering the work of his analyst-mentor, Anna Freud, who in 1936 had written ego psychology’s basic theoretical treatise, *The Ego and The Mechanisms of Defense.*

EIGHT STAGES OF THE LIFE CYCLE

Erikson’s conceptualization of psychosocial development across the life cycle is the centerpiece of his life’s work, and he elaborated the conception throughout his subsequent writings. It takes as its model the epigenetic principle of organismic growth in utero. In Erikson's view, psychosocial growth occurs in phases, with individual aspects of development proceeding according to a predetermined timetable. Elements of each phase are present from birth and differentiate over time. Every phase has its own period of quiescence and critical ascendancy, and each is dependent on the proper development of the other phases in the proper sequence. Work on any particular phase, Erikson theorized, is never complete, and old developmental conflicts can be activated by critical life events.

The eight stages of the life cycle represent points along a continuum of development in which physical, cognitive, instinctual, and sexual changes combine to trigger an internal crisis whose resolution results in either psychosocial regression or growth and the development of specific *virtues*. In *Insight and Responsibility,* Erikson defined virtue as "inherent strength," as in the active quality of a medicine or a liquor. He wrote in *Identity: Youth and Crisis* that "crisis" refers not to a "threat of catastrophe, but to a turning point, a crucial period of increased vulnerability and heightened potential, and therefore, the ontogenetic source of generational strength and maladjustment." Elsewhere, Erikson averred, "…we do not consider all development a series of crises: we claim only that psychosocial development proceeds by critical steps—"critical" being a characteristic of turning points, of moments of decision between progress and regression, integration and retardation." A child's experience of each crisis or critical turning point is affected by the attitudes of its parents and the values and customs of its culture.

Trust versus Mistrust (Birth to about 18 Months) In *Identity: Youth and Crisis*, Erikson noted that the infant "lives through and loves with" its mouth. Indeed, the mouth forms the basis of its first *mode* or pattern of behavior, that of incorporation. The infant is taking the world in through the mouth, eyes, ears, and sense of touch. The baby is learning a cultural modality that Erikson termed *to get*, that is, to receive what is offered and elicit what is desired. As the infant's teeth develop and it discovers the pleasure of biting, it enters the second oral stage, the active-incorporative mode. The infant is no longer passively receptive to stimuli; it reaches out for sensation and grasps its surroundings. The social modality shifts to that of *taking and holding on* to things.

The infant's development of basic trust in the world stems from its earliest experiences with its mother or primary caretaker. In *Childhood and Society,* Erikson asserts that trust depends not on "absolute quantities of food or demonstrations of love, but rather on the quality of maternal relationship." A baby whose mother is able to anticipate and respond to its needs in a consistent and timely manner despite its oral aggression will learn to tolerate the inevitable moments of frustration and deprivation. The defense mechanisms of introjection and projection will provide the infant with the means to internalize pleasure and externalize pain such that "consistency, continuity, and sameness of experience provide a rudimentary sense of ego identity." Trust will predominate over mistrust, and hope will crystallize. For Erikson, the element of society corresponding to this stage of ego identity is religion, as both are founded upon "trust born of care."

In keeping with his emphasis on the epigenetic character of psychosocial change, Erikson conceived of many forms of psychopathology as examples of what he termed *aggravated development crisis*, development that, having gone awry at one point, affects subsequent psychosocial change. A person who, as a result of severe disturbances in the earliest dyadic relationships, fails to develop a basic sense of trust or the virtue of hope may be predisposed as an adult to the profound withdrawal and regression characteristic of schizophrenia. Erikson hypothesized that the depressed patient's experience of being empty and worthless is an outgrowth of a developmental derailment that causes oral pessimism to predominate. Addictions may also be traced to the mode of oral incorporation.

Autonomy versus Shame and Doubt (about 18 Months to About 3 Years) In the development of speech and sphincter and muscular control, the toddler practices the social modalities of *holding on and letting go* and experiences the first stirrings of the virtue that Erikson termed *will*. Much depends on the amount and the type of control exercised by adults over the child. Control that is exerted too rigidly or too early defeats the toddler’s attempts to develop its own internal controls, and regression or false progression results. Parental control that fails to protect the toddler from the consequences of his or her own lack of self-control or judgment can be equally disastrous to the child’s development of a healthy sense of autonomy. In *Identity: Youth and Crisis*, Erikson asserted: “This stage, therefore, becomes decisive for the ratio between cooperation and willfulness, and between self-expression and compulsive self-restraint or meek compliance.”

Where that ratio is favorable, the child will develop an appropriate sense of autonomy and the capacity to “have and to hold”; where it is unfavorable, doubt and shame will undermine free will. According to Erikson, the principle of law and order has at its roots this early preoccupation with the protection and regulation of will. In *Childhood and Society*, he concluded, “[T]he sense of autonomy fostered in the child and modified as life progresses, serves (and is served by) the preservation in economic and political life of a sense of justice.”

An individual who becomes fixated on the transition between the development of hope and autonomous will, with its residue of mistrust and doubt, may develop paranoiac fears of persecution. When psychosocial development is derailed in the second stage, delinquency and other forms of pathology may emerge. The perfectionism, inflexibility, and stinginess of the person with an obsessive-compulsive personality disorder may stem from conflicting tendencies to hold on and to let go. The ruminative and ritualistic behavior of the person who suffers from an obsessive-compulsive disorder may be an outcome of the triumph of doubt over autonomy and the subsequent development and retention of a primitively harsh conscience.

Initiative versus Guilt (about 3 years to about 5 Years) The child’s increasing mastery of locomotor and language skills expands its participation in the outside world and stimulates omnipotent fantasies of wider exploration and conquest. Here the youngster’s mode of participation is active and intrusive; its social modality is that of *being on the make*. The intrusiveness is manifested in the child’s fervent curiosity and genital preoccupations, competitiveness, and physical aggression. The Oedipus complex is in ascendance as the child competes with the same-sex parent for the fantasized possession of the other parent. In *Identity: Youth and Crisis*, Erikson wrote that “Jealousy and rivalry… now come to climax in a final contest for a favored position with one of the parents: the inevitable and necessary failure leads to guilt and anxiety.”

Guilt over the drive for conquest and anxiety over the anticipated punishment are both assuaged in the child through repression of the forbidden wishes and the development of a superego to regulate its initiative. This conscience, the faculty of self-observation, self-regulation, and self-punishment, is an internalized version of parental and societal authority. Initially, the conscience is harsh and uncompromising; however, it constitutes the foundation for the subsequent development of morality. Having renounced oedipal ambitions, the child begins to look outside the family for arenas in which it can compete with less conflict and guilt. This is the stage that highlights the child’s expanding initiative and forms the basis for the subsequent development of realistic ambition and the virtue of *purpose*. As Erikson noted in *Childhood and Society*, “[T]he “oedipal” stage…sets the direction toward the possible and the tangible which permits the dreams of early childhood to be attached to the goals of an active adult life.” Toward this end, social institutions provide the youngster with an economic ethos in the form of adult heroes who begin to take the place of their storybook counterparts.

When there has been an inadequate resolution of the conflict between initiative and guilt, the individual may ultimately develop a conversion disorder, inhibition, or phobia. Those who overcompensate for the conflict by driving themselves too hard may experience so much stress as to produce psychosomatic symptoms.

Industry versus Inferiority (about 5 Years to about 13 Years) With the onset of latency, the child discovers the pleasures of production. He or she develops industry by learning new skills and takes pride in the things made. Erikson wrote in *Childhood and Society* that the child’s “ego boundaries include his tools and skills: the work principle…teaches him the pleasure of work completion by steady attention and persevering diligence.” Across cultures, this is a time when the child receives systematic instruction and learns the fundamentals of technology as they pertain to the use of basic utensils and tools. As children work, they identify with their teachers and imagine themselves in various occupational roles.

If the child is unprepared for this stage of psychosocial development, either through an insufficient resolution of previous stages or by current interference, the child may develop a sense of inferiority and inadequacy. Teachers and other role models help to transmit social values and become crucially important in the child's ability to overcome a sense of inferiority and to achieve the virtue known as *competence*. In *Identity: Youth and Crisis*, Erikson noted: "[T]his is socially a most decisive stage. Since industry involves doing things beside and with others, a first sense of division of labor and of differential opportunity, that is, a sense of the technologic ethos of a culture, develops at this time."

The pathologic outcome of a poorly navigated stage of industry versus inferiority is less well defined than in previous stages, but it may concern the emergence of a conformist immersion into the world of production in which creativity is stifled, identity is subsumed under the worker's role, and feelings of inferiority are warded off through a defensive preoccupation with status and compensation.

Identity versus Role Confusion (about 13 Years to about 21 Years) With the onset of puberty and its myriad social and physiologic changes, the adolescent becomes preoccupied with the question of identity. Erikson noted in *Childhood and Society* that youth are now "primarily concerned with what they appear to be in the eyes of others as compared to what they feel they are, and with the question of how to connect the roles and skills cultivated earlier with the occupational prototypes of the day." Childhood roles and fantasies are no longer appropriate, yet the adolescent is far from equipped to become an adult. In *Childhood and Society,* Erikson writes that the integration that occurs in the formation of ego identity encompasses far more than the summation of childhood identifications. "It is the accrued experience of the ego's ability to integrate these identifications with the vicissitudes of the libido, with the aptitudes developed out of endowment, and with the opportunities offered in social roles.” Coles explains that ego identity is an “accrued confidence” which develops over time and crystallizes in early adulthood—or does not. It is the confidence that “… somehow in the midst of change one *is*; that is, one has an “inner sameness and continuity” which others can recognize and which is so certain that it can unselfconsciously be taken for granted.”

The formation of cliques and the intolerance of individual differences are ways in which the young person attempts to ward off a sense of identity confusion. In *Childhood and Society*, Erikson noted:

> For adolescents not only help one another temporarily through much discomfort by forming cliques and by stereotyping themselves, their ideals, and their enemies; they also perversely test each other’s capacity to pledge fidelity. The readiness for such testing also explains the appeal that simple and cruel totalitarian doctrines have on the minds of the youth of such countries and classes as have lost or are losing their group identities (feudal, agrarian, tribal, national) and face worldwide industrialization, emancipation, and wider communication. (Excerpt from Erikson EH. *Childhood and Society*. W.W Norton & Company; 1963.)

Falling in love, a process by which the adolescent may clarify a sense of identity by projecting a diffused self-image onto the partner and seeing it gradually assume a more distinctive shape, and an overidentification with idealized figures are means by which the adolescent seeks self-definition. With the attainment of a more sharply focused identity, the youth develops the virtue of *fidelity*—a faithfulness not only to the nascent self-definition but to an ideology that provides a version of self-in-world. As Erikson, Joan Erikson, and Helen Kivnick wrote in *Vital Involvement in Old Age*: “[F]idelity is the ability to sustain loyalties freely pledged in spite of the inevitable contradictions of value systems. It is the cornerstone of identity and receives inspiration from confirming ideologies and affirming companionships.”

Role confusion ensues when the youth is unable to formulate a sense of identity and belonging. Coles explains:

> In a state of “acute identity diffusion” the young individual may feel isolated, empty, anxious, and unable to make decisions that he (let alone his parents or

> teachers) feels pending. He wants "out," he wants to be away, he wants "time" to think and decide and only later act. (Excerpted from Coles R. *Erik H. Erikson: The Growth of His Work*. Little, Brown and Company; 1970.)

Erikson held that delinquency, gender-related identity disorders, and borderline psychotic episodes can result from such confusion.

Intimacy versus Isolation (about 21 Years to about 40 Years) Freud's famous response to the question of what a normal person should be able to do well, "Lieben und arbeiten" (to love and to work), is one that Erikson often cited in his discussion of this psychosocial stage, and it emphasizes the importance he placed on the virtue of *love* within a balanced identity. Erikson asserted in *Identity: Youth and Crisis* that Freud's use of the term love referred to "the generosity of intimacy as well as genital love; when he said love and work, he meant a general work productivity which would not preoccupy the individual to the extent that he might lose his right or capacity to be a sexual and a loving being."

Intimacy in the young adult is closely tied to fidelity; it is the ability to make and honor commitments to concrete affiliations and partnerships even when that requires sacrifice and compromise. The person who cannot tolerate the fear of ego loss arising out of experiences of self-abandonment (e.g., sexual orgasm, moments of intensity in friendships, aggression, inspiration, and intuition) is apt to become deeply isolated and self-absorbed. *Distantiation,* an awkward term coined by Erikson to mean "the readiness to repudiate, isolate, and, if necessary, destroy those forces and people whose essence seems dangerous to one's own," is the pathologic outcome of conflicts surrounding intimacy and, in the absence of an ethical sense where intimate, competitive, and combative relationships are differentiated, forms the basis for various forms of prejudice, persecution, and psychopathology.

Erikson's separation of the psychosocial task of achieving identity from that of achieving intimacy and his assertion that substantial progress on the former task must precede development on the latter have engendered much criticism and debate. Critics have argued that Erikson's emphasis on separation and occupationally based identity formation fails to take into account the importance for women of continued attachment and the formation of an identity based on relationships.

Generativity versus Stagnation (about 40 Years to about 60 Years) Erikson asserted in *Identity: Youth and Crisis* that "Generativity…is primarily the concern for establishing and guiding the next generation." The term *generativity* applies not so much to rearing and teaching one's offspring as to a protective concern for all the generations and for social institutions. It encompasses productivity and creativity as well. Having previously achieved the capacity to form intimate relationships, the person now broadens the investment of ego and libidinal energy to include groups, organizations, and society. *Care* is the virtue that coalesces at this stage. In *Childhood and Society,* Erikson emphasized the importance to the mature person of feeling needed. "[M]aturity needs guidance as well as encouragement from what has been produced and must be taken care of." Through generative behavior, the individual is able to pass on knowledge and skills while obtaining a measure of satisfaction in having achieved a role with senior authority and responsibility in the tribe.

When people are unable to develop true generativity, they may settle for pseudo-engagement in occupation. Often such people restrict their focus to the technical aspects of their roles at which they may now have become highly skilled, eschewing larger responsibility for the organization or profession. This failure of generativity can lead to profound personal stagnation, masked by a variety of escapisms, such as alcohol and drug abuse and sexual and other infidelities. A midlife crisis or premature invalidism (physical and psychological) may occur. In this case, pathology appears not only in middle-aged persons but also in the organizations that depend upon them for leadership. Thus, the failure to develop at midlife can lead to sick, withered, or destructive organizations that spread the effects of failed generativity throughout society; examples of such failures have become so common as to constitute a defining feature of modernity.

Integrity versus Despair (about 60 Years to Death) In *Identity: Youth and Crisis*, Erikson defined integrity as “the acceptance of one’s one and only life cycle and of the people who have become significant to it as something that had to be and that, by necessity, permitted of no substitutions.” From the vantage point of this stage of psychosocial development, the individual relinquishes the wish that important people in his life had been different and is able to love in a more meaningful way—one that reflects an acceptance of responsibility for one’s own life. The individual in possession of the virtue of *wisdom* and a sense of integrity has room to tolerate the proximity of death and to achieve what Erikson termed in *Identity: Youth and Crisis* a “detached yet active concern with life.” Despair may be present, but it does not predominate.

Erikson underlined the social context for this final stage of growth. In *Childhood and Society*, he wrote, “The style of integrity developed by his culture or civilization thus becomes the “patrimony” of his soul…In such final consolidation, death loses its sting.”

When the attempt to attain integrity has failed, the individual may become deeply disgusted with the external world and contemptuous of persons as well as institutions. Erikson wrote in *Childhood and Society* that such disgust masks a fear of death and a sense of despair that “time is now short, too short for the attempt to start another life and to try out alternate roads to integrity.” In thinking about the relationship between adult integrity and infantile trust, Erikson observed, “[H]ealthy children will not fear life if their elders have integrity enough not to fear death.”

BECOMING A BIOGRAPHER OF YOUTH

In 1949, as *Childhood and Society* was going to press, Erikson’s stand on the University of California loyalty oath had rendered his position at the university untenable. News of his availability spread east, and other institutions vied to capitalize on Berkeley’s mistake. Erikson was well known at the Menninger Clinic in Topeka, Kansas, where he had lectured, so when Robert Knight left Menninger to become the director of the Austen Riggs Center in Stockbridge, Massachusetts, he took Erikson with him. The Austen Riggs Center was devoted to psychoanalytic research and to the treatment of severely disturbed adolescents and young adults—Erikson had been happily adopted once again.

Erikson stayed at Austen Riggs from 1950 to 1960, from age 48 to 58, when he returned to the faculty of Harvard University. During those years, Erikson completed the transition to biographer, forming more fully the approach foreshadowed in his incomplete essays on Hitler, Gorky, and George Bernard Shaw. The transition was not easy; Coles describes that time as constituting a second "identity crisis." Erikson had been a clinician and a theorist of youth; he was now old enough to enact the program promised in *Childhood and Society* and to become a biographer and theorist of the whole life cycle. However, before he wrote *Young Man Luther*, he once again returned to Freud and the origins of his own professional identity. The way to the future was through the past.

In his early 50s, Erikson wrote three biographical essays on Freud: "The Dream Specimen of Psychoanalysis," "Freud's 'The Origins of Psychoanalysis,'" and "The First Psychoanalyst." These essays all concern themselves with the crisis Freud suffered during his own midlife transition as he struggled to leave neuropathology and to define a new professional identity as a psychoanalyst. Strengthened by that re-examination of Freud's successful transition (and perhaps having reassured himself of Freud's blessing), Erikson began writing one of the genuine masterworks of psychoanalysis, *Young Man Luther.*

As always, Erikson's clinical work and observations enriched his theorizing about the life cycle. He acknowledged his debt to Austen Riggs and the Western Psychiatric Institute at the University of Pittsburgh in his preface to *Young Man Luther*. His work there had allowed him to "study the afflictions of young patients as variations on one theme, namely, a life crisis, aggravated in patients, yet in some form normal for all youth. I could identify those acute life tasks that would bring young people to a state of tension in which some would become patients."

However, Erikson would neither make Martin Luther a patient nor reify the psychopathology of the young people who were his patients. Instead, he asserted that comparisons between Martin Luther and his patients were “not restricted to psychiatric diagnosis…but…oriented toward those moments when young patients, like young beings anywhere, prove resourceful and insightful beyond all professional and personal expectation. We will concentrate on the powers of recovery inherent in the young ego.”

Working with the young patients at Austen Riggs helped Erikson hone his understanding of identity formation. As he later put it in “The Problem of Ego Identity,” “[I]dentity…is gradually established by successive ego syntheses and resyntheses throughout childhood. It is a configuration gradually integrating *constitutional givens, idiosyncratic libidinal needs, favored capacities, significant identifications, effective defenses, successful sublimations, and consistent roles*.”

These “ego syntheses and resyntheses” were about to receive great attention as Erikson attempted his biography of Luther. But to do that work, Erikson, the biographer, had to move further away from his own professional origins as a child psychoanalyst. He had criticized psychoanalysis for its contention that something has been explained by finding an analogy to its earliest manifestations. Yet his own conception of the life cycle, with most of its stages occurring within the preadult era, left him still heavily rooted in childhood. In his study of Luther, Erikson was trying to understand a life, not just a personality; from that perspective, childhood and adolescence had to be introductory rather than the story itself.

Seeing that a child-centered view was not adequate for the tasks of biography, without either formally changing the imbalance in his theory or neglecting childhood determinants, Erikson deftly devoted the greatest attention to an explication of development in the adult years. So successful was he in interrelating Luther’s adult problems with those of his early development that *Young Man Luther* provided the seminal inspiration for the next generation of life-cycle investigators. Some of those investigators, such as Daniel Levinson, formally redressed in their own theories the originologic bias vestigial in Erikson's theories.

In Luther's early or mid-20s, according to some of his contemporaries, the young monk had fallen to the floor of the choir of his monastery in a fit and shouted, "ich bin's nit!" or "Non Sum!" "It isn't me," or "I am not." Erikson's task as a psychological biographer was to explain how Luther got from the identity crisis of his 20s to nailing his 95 theses to the door of the church in Wittenberg at the age of 32. Yet *Young Man Luther* is also, as it is subtitled, "a study in psychoanalysis and history." Since it is not a psychoanalysis of history, some nonreductionist connecting concepts between the individual and the collectivity were needed. One of Erikson's connecting concepts was *ideology*, which he defined as "an unconscious tendency underlying religious and scientific as well as political thought: the tendency at a given time to make facts amenable to ideas, and ideas to facts, in order to create a world image convincing enough to support the collective and the individual sense of identity."

Luther had personal and psychiatric problems, but in his defiance of Catholic orthodoxy, he created a new religious ideology that not only supported his own identity but the identities of emerging generations of Europeans as well. "Ich bin's nit" expressed the young monk's identity crisis as he found himself "fatally over-committed" to what he was not, a young man authentically embarking on a future as an orthodox Catholic priest. "In some periods of history," Erikson asserted, "and in some phases of his life cycle, man needs…a new ideologic orientation as surely and as sorely as he must have air and food." As such a man, Luther commanded Erikson's "sympathy and empathy" as he "faced the problems of human existence in the most forward terms of his era."

The reception of the book cemented Erikson's international reputation, initially won by *Childhood and Society*, as a leader in original, humane thought about psychological development. In no other biography have the dynamics of individual conflict and development been so seamlessly interwoven with those of society and history. With *Young Man Luther*, Erikson in his late 50s ascended from the first rank of developmental psychoanalysts to that of a cultural seer.

BECOMING A BIOGRAPHER OF MIDDLE AGE

As Erikson moved through the transition from middle to old age, he abandoned clinical work with patients to turn his attention fully to the study of the life cycle and the survival of the species. His emphasis, emergent in *Young Man Luther* and implicit in all his earlier work, was on the ego virtues that permit a person to live in a constructively critical relationship with the social institutions of his time. Earlier, Erikson had described the stages in the development of the ego across the life cycle. In 1964 he wrote more about the ego virtues in *Insight and Responsibility*. He was getting ready amidst the American moral and political crises of the mid-1960s to embark on his last major work, a study of the great moral leader Mohandas Gandhi. In the end, he dedicated it, *in memoriam*, to Martin Luther King, Jr.

Young Man Luther had been a story of personal choice and historical change wrought by a young man establishing and revising an initial identity and life structure as an adult. In his mid-60s, Erikson had gained sufficient perspective on the life cycle to analyze a case of decisive crisis and change in a man who was going through a midlife transition and solving it by creating a vital life structure for middle age. Gandhi did that, as he himself put it, by realizing “his vocation in life,” leading *satyagraha* truth-force campaigns in his nation, in his family, and in his own soul. Gandhi was entering the stage of the life cycle in which Erikson’s ego polarity of *generativity versus stagnation* becomes active; from his developmental work on this polarity, Gandhi was learning the ego virtue of *care*.

Erikson saw that Gandhi, like Luther, was both a leader and a “religious actualist.” As a leader, he succeeded in articulating inner concerns in a way that struck a collective cord. Self-rule and home rule were inextricably combined in Gandhi’s program. He would have endorsed in his own terms, Erikson believed, Luther’s assertions, "Christ comes today; God's way is what makes us move; we must always be reborn, renewed, regenerated; to do enough means nothing else than always to begin again."

Gandhi had begun and successfully completed his political novitiate as an Oxford-trained barrister in South Africa during his 20s and 30s. By his late 30s, he had developed passive resistance as a political strategy to defeat the Black Act, a law that required all Indians in the Transvaal to register with the government and to carry identification papers on their persons. At 40, Gandhi staked out his claim for leadership in his Indian Home Rule Manifesto, and during the next few years of his midlife transition, he developed the device of the Satyagraha campaign, culminating in the Great March of striking mineworkers in South Africa when he was 44.

When Gandhi returned to India in 1915 at age 45, he did so, Erikson wrote, "like a man who knew the nature and the extent of India's calamity and that of his own fundamental mission." As a mature, middle-aged man, he was, in Erikson's view, a person who has determined what "he does and does not *care for*" as well as "what he *will* and *can* take *care of*. He takes as his baseline what he irreducibly is and reaches out for what only he can, and therefore, *must* do."

What Gandhi had to do was lead a labor strike at the mills in Ahmedabad and the next year, at age 50, a national strike for independence from Britain. Erikson contended that Gandhi's emergence at that time as the "father of his country" underlined "the fact that the middle span of life is under the dominance of the universal human need and strength which I have come to subsume under the term *generativity*." Erikson refers here not merely to the generativity that a parent at 20 or 30 may feel for a child. Erikson's concept of generativity is often mistakenly taken to apply to the child-rearing work of young adults. Instead, he is describing the protective concern for the generations and their retarding-facilitating social institutions, whose leadership is the essential responsibility of the middle-aged individual.

In the early 1970s, Erikson returned to the San Francisco Bay Area to live and begin again. The Eriksons relocated to Cambridge, Massachusetts, some 10 years later. In 1981 the Eriksons and psychologist Helen Kivnick undertook an intensive study of 29 octogenarian parents of children whose lives had been meticulously scrutinized in the Guidance Study begun in 1928 at the Institute of Human Development at the University of California at Berkeley. The results of their research were published in *Vital Involvement in Old Age.*

In this work, Erikson, Erikson, and Kivnick revisit the eight stages of psychosocial development and their attendant virtues or strengths. They emphasize the opportunities that exist at the end of life to integrate “maturing forms of hope, will, purpose, competence, fidelity, love, and care into a comprehensive sense of wisdom.” A successful integration results from a final reworking of the earlier polarities of basic trust versus mistrust; autonomy versus shame and doubt; initiative versus guilt; industry versus inferiority; identity versus confusion; intimacy versus isolation; generativity versus self-absorption; and integrity versus despair. The authors use the term *vital involvement* to identify an involvement with the environment characterized by “actuality” and “mutuality.” The elder who is able to maintain a vital involvement with his world—no matter how small its scope—is better able to tolerate the depredations of aging: the loss of sensory acuity, physical mobility, and stamina; changes in intimate relationships as children marry and move away, and friends and partners sicken and die; the loss of social status, financial security, and sources of pride in professional competence; and the realization that relatively little time remains.

Developed in infancy, hope is the basis upon which the senescent individual attempts to integrate faith in the universe and the relative predictability of its laws, with a realistic mistrust about that which is unpredictable and unreliable. The elder may experience a need to affirm a basic faith—in religion or nature—and to understand more deeply his own place in a generational progression.

Late in life, the individual must struggle to redefine a sphere of autonomy even as he becomes increasingly dependent upon others. Living independently, residing in familiar surroundings, and following established routines can be crucial symbols of autonomy and the means by which signs of impairment (e.g., a walker) may be accepted without undue shame. An individual’s lifelong experience of autonomy influences his or her capacity to adjust to restrictions upon freedom. The ability to allow others to help supports the generative impulses of younger adults and reinforces for both the sense of a generational cycle.

The polarities of initiative versus guilt, first evident in the youngster’s exploration and play and subsequently in adult work and recreation, must be balanced anew in old age. With the passage of time, the person faces a diminution of opportunities for the exercise of initiative and must regret those instances where he or she failed to act decisively or with sufficient concern for others. Successful adaptation to the limitations of old age must draw upon the strength of purposefulness developed in childhood and tempered by maturity.

With the natural decline in physical strength and sensory acuity, the senescent individual increasingly depends upon a lifelong sense of effectiveness. External rewards are usually not as numerous as they were in young adulthood or middle age. The feeling of competence and mastery must be sustained internally. An old person may cope with growing physical limitations by changing the criteria for a sense of accomplishment, pursuing new hobbies or modifying old ones, developing new avenues of involvement with former professions, or living vicariously through the accomplishments of children and grandchildren.

Old age provides the individual with the chance to review a lifetime of beliefs, to come to terms with choices made and opportunities lost, and to make and act upon any final commitments, which now most clearly reflect what Erikson termed “the ‘I’ in the totality of life.” In striking a final balance between identity and identity confusion, the elder concerns himself with both an external image and a personal image. The external image is the way the individual may expect to be remembered; the personal image reconciles the sense of who he or she has been with an evolving sense of whom he or she may yet become. Identification with the successes of younger generations and satisfaction in one’s own part in the transmission of values helps the senescent to stave off feelings of insignificance or obsolescence in the face of technologic and sociologic changes.

The sense of love that can emerge at the end of life is one that is built upon a foundation of love, expressed and unexpressed, throughout the life cycle. A new balance may be forged between intimacy and isolation in the face of decline. Intimate relationships may be recast in more positive terms; reminiscences provide the elder with the opportunity to draw upon and reintegrate earlier experiences of tenderness and sexuality.

In order to reconcile feelings of integrity and despair, the individual must make peace with previous choices, acknowledging what was gained and lost and accepting that it is too late to change. Relationships and values may be reviewed with more room to consider alternate points of view. In balancing the dispositions toward generativity and stagnation, the older adult may be able to build upon years of experiences as a parent, worker, and creatively productive person from middle age, which themselves were shaped by childhood experiences of caring or its absence. Grandparenthood offers another chance at generativity and a way to undertake it more robustly and less ambivalently. Erikson coined the term “grand-generativity” to distinguish the generativity of old age in which the person, freed from the direct responsibility for family, institution, and community, is better able to incorporate care for the present with concern for the future. Such concern may be expressed through advice or financial assistance to family members or, on a larger scale, through a commitment to religious beliefs, political involvement, or community action. Grand-generativity contributes to a feeling of immortality; in caring for the younger generation and allowing oneself to be taken care of, the senescent secures a personal place in a generational history.

The “joint reflections of old age” contained in the book are an effort to elucidate the psychosocial process of vital involvement and to extend Erikson’s observations to the outer limits of the life cycle. The book also brought Erikson back full circle to his professional beginnings—having made almost 40 years earlier, play observations on the Guidance Study children.

ERIKSON AND CULTURE

Erikson has been a pioneer in alerting psychotherapists, especially of the psychodynamic persuasion, to the role of culture in constructing the psyche. This understanding is a consequence of his recommendation to therapists (and psychobiographers) that the meaning of an “event” in a patient’s life needs to be understood in a fourfold configuration of meaning: the meaning of the event at the stage of the patient’s life cycle, its meaning in the patient’s life history, its meaning in the patient’s culture, and its meaning in the history of the culture. He alerts us that the terroir of psychotherapy for more than a century has been and continues to be Western, with its centers located in North America, United Kingdom, and North and Central Europe. It contains many Western cultural ideas and ideals that permeate psychotherapeutic theories and practices. Shared by therapist and patient alike, pervading the therapeutic space in which the two are functioning, fundamental ideas about human relationships, family, marriage, male and female, on what constitutes psychological maturity and so on which are essentially cultural in origin often remain unexamined and regarded as universally valid. Examples include how to behave toward superiors and subordinates in organizations, the kinds of food conducive to health and vitality, and the family’s web of duties and obligations. All these are as much influenced by the cultural part of the mind as are ideas concerning the proper relationship between the sexes or one’s relationship to the Divine.

However, Erikson is not a complete relativist but introduces the notion of psychic universals lying on a continuum rather than occupying a fixed point. To illustrate, take the example of the universal psychic phenomenon of separation-individuation. Between a minimum of separation-individuation needed to function as an adult in a particular society and a maximum that cuts off all ties with family and community, there is a range of positions. Psychoanalysis should recognize the positions as part of being human rather than closely identifying with any particular position on the continuum as the only one that is “healthy and mature.”

Take another example that is fundamental for our psychic makeup and how we view the world: gender.

Unconsciously absorbed since childhood, our culture determines what it means to be, look, think, or behave like a man or a woman. This concept becomes more apparent if one thinks of Greek or Roman sculpture with their hard, muscled men's bodies and chests without any fat (familiar to Europeans and Americans from childhood visits to the museum or reproduced in countless visual mediums) and compare it with the sculpted representations of Hindu gods or the Buddha, where the bodies are softer, suppler, and, in their hint of breasts, nearer to the female form. Between a minimum of sexual differentiation needed to function heterosexually with a modicum of pleasure and a maximum that cuts off any sense of empathy and emotional contact with the other sex experienced as a different species altogether, there is a whole range of positions, each occupied by a culture that assumes it is universal and insists on calling it the only one that is mature and healthy.

In a postcolonial, globalizing world, steering between the extreme universalist and relativistic positions, Erikson's contributions to the role of culture in the formation of the psyche can be invaluable in reconsidering many psychotherapeutic assumptions and models.

APPLICATION OF ERIKSON'S CONCEPTS TO CLINICAL WORK

Erikson's view of individual experience as inexorably embedded in developmental, familial, societal, and historical contexts crucially shaped his ideas concerning mental illness and psychiatric treatment. As noted previously, Erikson was reluctant to pathologize behavior or to rush to judgment about the meaning of any given symptom. He asserted, "Perhaps there are certain stages in the life cycle when even seemingly malignant disturbances are more profitably treated as *aggravated life crises* rather than as diseases subject to routine psychiatric diagnosis."

To understand the meaning of such “disturbances,” Erikson drew upon his training in classical drive theory (with its concepts of the unconscious; id, ego, and superego conflicts; repression, regression, and repetition compulsion) but emphasized the adaptive and synthesizing capacities of the ego in brokering relations between internal drives and external reality. When Erikson listened to his patients, he thought about their symptoms not simply as compromise formations between libidinal drive and superego prohibition but also as expressions of arrested or derailed psychosocial development. Toward this end, Erikson examined many aspects of his patient’s current life (e.g., skills, talents, and aspirations; religious and political commitments; social and intimate relationships; roles as worker, partner/spouse, and parent) and located them within a larger social, cultural, and historical context. His focus was on the individual’s entire life cycle, the development of specific virtues, and those factors which facilitated or retarded psychosocial growth. As Shapiro and Fromm point out:

> He paid attention to the whole life context of any immediate situation. He asked a number of questions. What is the immediate stimulus for the patient’s reaction? What is the acute life conflict, the current developmental stage, the issues that are manifest? In what developmental context did the patient’s reaction first occur? Is it now manifest in the relationship to the therapist, in a repetitive conflict, in a characteristic way that the individual solved earlier developmental struggles? In what social context is the individual embedded, what roles are available?…What defenses does the individual use? What are the individual’s deepest psychological investments?

Erikson conceived of these psychological investments in broad terms. He used concepts of attachment, separation, and mutuality (defined as “a relationship in which partners depend on each other for the development of their respective strengths”) to illustrate ways in which the individual is essentially a social being. He recognized that psychological crises often occurred at times of developmental separation or individuation and that fears regarding dependency and abandonment were frequently the catalyst for such crises. Though Erikson acknowledged the influence of early childhood conflict or trauma on an individual’s progress in negotiating developmental tasks in adolescence and adulthood, he did not think that the issues being played out were simply reiterations of infantile conflict.

Erikson's belief that psychosocial development continues throughout the life cycle led him to caution psychotherapists against a theoretical reductionism in which symptomatic behavior was attributed to a traumatic past and in which insufficient attention was paid to contemporary conflicts in the ego's relations with the world. He was particularly critical of the "originology" in psychoanalytic thought. "I mean by it a habit of thinking which reduces every human situation to an analogy with an earlier one, and most of all to that earliest, simplest and most infantile precursor which is assumed to be its "origin."" Erikson was wary of other theoretical blindspots within his profession. As Coles noted, "…psychiatric and psychoanalytic concepts emerge from and become very much suited to a particular society—which exerts its (moral and puritanical) influence on everything, even the most complicated, rarefied, and "objective" of abstractions."

In his article, *The Nature of Clinical Evidence*, Erikson outlined the relationship between patient and therapist. He described the "clinical core of medical work" as the

> "encounter of two people, one in need of help, the other in the possession of professional methods. Their *contract* is a therapeutic one: in exchange for a fee, and for information revealed in confidence, the therapist promises to act for the benefit of the individual patient, within the ethos of the profession." (Excerpted from Erikson EH. The nature of clinical evidence. *Daedalus*. 1958;87(4):65–87. © 1958 American Academy of Arts & Sciences, with permission. http://www.jstor.org/stable/20026463.)

Though he acknowledged certain parallels between medical and psychiatric consultations (e.g., the patient presents with a list of symptoms, the physician/psychiatrist asks questions designed to elucidate the problems, arrives at a tentative diagnosis, and proposes a treatment plan), Erikson departed from a traditional medical model in important ways. Though according to the therapist the respect and authority appropriate to his special training and expertise, Erikson envisioned the patient as an active participant in a collaborative endeavor. Within the limitations imposed by the treatment setting (e.g., inpatient vs. outpatient) and degree of psychological impairment, the patient was expected to take significant responsibility for his treatment. Erikson noted a natural transformation that occurs in the patient.

> ““Under observation,” he becomes self-observant. As a patient he is inclined, and as a client often encouraged, to historicize his own position by thinking back to the onset of the disturbance, and to ponder what world order (magic, scientific, ethical) was violated and must be restored before his self-regulation can be reassumed.” (Excerpt from Erikson EH. *Insight and Responsibility: Lectures on the Ethical Implications of Psychoanalytic Insight*. W.W. Norton & Company; 1964.)

How does the patient participate in his own “cure”? He is invited to free associate. Erikson noted, “(W)e consider a patient’s “associations” our best leads to the meaning of an as yet obscure item brought up in a clinical encounter, whether it is a strong affect, a stubborn memory, an intensive or recurring dream, or a transitory symptom.” The associations consist of whatever thoughts, feelings, sensations, or images occur to the patient during and after the mention of that item. Erikson continued,

> “Except in cases of stark disorganization of thought, we can assume that what we call the synthesizing function of the ego will tend to associate what “belongs together,” be the associated items ever so remote in history, separate in space, and contradictory in logical terms…It is…this basic synthesizing trend in clinical material itself that permits the clinician to observe with “free-floating attention,” to refrain from undue interference, and to expect sooner or later a confluence of the patient’s search for curative clarification and his own endeavor to recognize and to name what is most relevant, that is, to give an *interpretation*.” (Excerpt from Erikson EH. *Insight and Responsibility: Lectures on the Ethical Implications of Psychoanalytic Insight*. W.W. Norton & Company; 1964.)

Free-floating attention “turns inward to the observer’s ruminations even as it attends the patient’s “free associations’ and which, far from focusing on any item too intentionally, rather waits to be impressed by recurring themes.” A message represented by a patient’s memory, dream image, or symptom can be overdetermined —“a condensed code transmitting a number of other messages, from other life situations, seemingly removed from the therapy. This we call “transference.””

As for the therapist’s role in working with the patient’s free associations, Erikson averred,

> “I have to assume that the patient is (to varying degrees) unconscious of the meaning which I discern in his communications, and that I am helping him by making fully conscious what may be totally repressed, barely conscious, or simply cut off from communication…I take for granted an effective wish on his part (with my help) to see, feel and speak more clearly.” (Excerpt from Erikson EH. *Insight and Responsibility: Lectures on the Ethical Implications of Psychoanalytic Insight*. W.W. Norton & Company; 1964.)

Erikson felt that a “therapeutic” interpretation was one which was clear and concise, yet presented the patient with a “unitary” theme, “…a theme common at the same time to a dominant trend in the patient’s relation to the therapist, to a significant portion of his symptomatology, to an important conflict of his childhood, and to corresponding facets of his work and love life.” How would the therapist determine if an interpretation was “right”? Erikson believed, “(T)he proof lies in the way in which the communication between therapist and patient “keeps moving,” leading to new and surprising insights and to the patient’s greater assumption of responsibility for himself.”

Erikson acknowledged that there was a great deal of subjectivity involved in both the patient’s complaints and the therapist’s interpretations. He cautioned, “…even while facing most intimate and emotional matters, (the therapist) must maintain intellectual inner contract with his conceptual models, however crude they may be.” He must evince “…a *specific self-awareness* in the very act of perceiving his patient’s actions and reactions.” Erikson wrote, “…there is a core of *disciplined subjectivity* in clinical work–and this both on the side of the therapist and of the patient—which it is neither desirable nor possible to replace altogether with seemingly more objective methods.” The therapist was advised to undergo a personal psychoanalysis in order to reduce or eliminate potential blindspots which might compromise this disciplined subjectivity.

Erikson noted “the power of the transference, that is, the patient’s transfer to me of significant problems in his past dealings with the central people in his life” but also conceived of what we would now call a “real” relationship between himself and his patient. In *The Nature of Clinical Evidence*, Erikson provided a lengthy clinical vignette illustrating dream analysis and his use of his emotional reactions in his interpretations to his patient. Because he did not conceive of clinical work as primarily oriented toward the development and interpretation of the transference, Erikson accorded himself and other clinicians the freedom to cultivate “real” aspects of the relationship with the patient. He felt it important and necessary at times that the therapist educate and guide his patient. Erikson averred, “…only by playing my role as a new person in his present stage of life can I clarify the inappropriateness of his transferences from the past.”

A psychotherapy informed by Eriksonian principles is essentially optimistic in nature. For it takes as a given the notion that psychosocial development is universal and continues throughout the life cycle. Natural forces propel the individual forward. Psychiatric symptoms are often best understood as manifestations of aggravated developmental crises—development that has been blocked or derailed. In such cases, the therapeutic task is to release or redirect those built-in forces for growth and adaptation.

As Erikson noted in *Identity: Youth and Crisis*, the object of psychotherapy is not to head off future conflict but to assist the patient in emerging from each crisis “with an increased sense of inner unity, with an increase of good judgment, and an increase in the capacity “to do well” according to his own standards and to the standards of those who are significant to him.”

6.3 Other Psychodynamic Schools

KRISTINE L. MCCASLIN, PSY.D., AND ADAM M. BRENNER, M.D.

The professionals discussed in this chapter—Adolf Meyer, Alfred Adler, Carl Gustav Jung, Franz Alexander, Wilhelm Reich, Karen Horney, Erich Fromm, Harry Stack Sullivan, Eric Berne, and Nancy Chodorow—expanded psychiatric thought and practice throughout the 20th century and into the 21st. With knowledge of the neurosciences initially primitive, the ethos of psychiatry was to use clinical observation to search for an overarching theory that would encompass not only psychopathology but all of human behavior. None of these individuals doubted that the mind has a biologic basis, but they all were aware of Sigmund Freud's woeful failure in his *Project for a Scientific Psychology* to develop an understanding of how experience, thoughts, and feelings are transduced to and from material states. Because of this, they were forced to stand back from the physical organism and view humans strictly as psychological entities. What, then, is the relevance of these theories to 21st-century psychiatry? Are these theories of merely historical interest, or do they hold some wisdom for current clinical practice? Until 30 years ago, psychiatrists spent great time and energy comparing and contrasting theorists and arguing the pros and cons of various formulations. Within psychoanalysis and other "schools" of psychotherapy, such theoretical discussions still occur. Now, however, the primary contribution of these theorists is in their broad brush strokes; for example, should one embrace the frustration model of classical psychoanalysis, the actively empathic model of self-psychology, or the interactive model of interpersonal psychiatry?

There is also a historical shift that has occurred. In the past, as a clinician contemplated some new insight into the workings of patients' inner lives, it was often seen as necessary, not only to build a new theory but also to create a new "school" of therapy. This may have been an outgrowth of Freud's personality, which tended to focus on his current line of observations and thought, thus forcing others (e.g., Adler and Jung) to move outside the inner circle to pursue their different lines of thinking. These days, psychoanalysis is a far more open intellectual enterprise, embracing a variety of different models and inputs.

These theories remain relevant in several important ways. First, regardless of what is learned about neurobiology, psychiatry is and will remain concerned with distress in behavior, thoughts, emotions, and relationships. Inevitably, these will be communicated through words and nonverbal signals. Psychiatrists will always need some organizing templates at the behavioral and verbal communicational levels to help order and interpret their observations. A sad, pensive, tearful expression does not automatically translate into a serotonin or norepinephrine deficiency or some other structural abnormality. It must first be translated into the psychological constructs of loss, depression, grief, and so forth. Second, these theorists spent enormous time listening to patients, and all were careful observers. As such, their observations remain helpful in defining key dimensions for psychiatrists to consider in understanding the inner experiences patients attempt to communicate. Finally, all of these theorists were well versed in a rigorous approach to theory construction. Every human being has a “theory of personality,” acknowledged or otherwise. This theory, often intuitive and unrigorous, based on a mixture of reading, personal values, and unsystematic observation, influences much of the way people interact with one another. In the clinical situation, when a psychiatrist mixes supportive management and medication, they are using a personal theory of personality. The advantage of knowing the theorists in this chapter is that models of intellectual rigor can be brought to personal intuitions.

The following case is used as a basis for formulation according to each theorist to illustrate the different understandings and therapeutic approaches of each theorist.

Mr. A was a 26-year-old White man who had a history of bipolar I disorder. He was brought in for treatment after not completing the last required course for his advanced degree and being arrested for disturbing the peace. He had consistently lied to his family about where he stood with his coursework and about having skipped an examination that would have qualified him to use his professional degree. He had also not told them that he had been using marijuana almost daily for a number of years and occasionally used hallucinogens. His arrest for disorderly conduct was for swimming naked in an apartment complex in the middle of the night while under the influence of hallucinogens.

Mr. A's use of marijuana began early in college but became daily during graduate school. He was diagnosed as having bipolar I disorder early in his senior year at college after a clear episode of mania. His mood disorder was well controlled on lithium (Eskalith). During graduate school, he was episodically adherent to taking medications, preferring to try to maintain a state of hypomania. He saw a psychiatrist every 3 to 6 months for medication management. During his 4 years in graduate school, he had two clear episodes of depression and began taking sertraline (Zoloft), 100 mg per day, with questionable benefit. Mr. A believed that he could be a great writer. He spent most of his time reading and trying to write. He dreamed of going to New York or Paris and becoming part of a new wave of novelists. This aspiration and his marijuana abuse predated his development of bipolar I disorder. He attended class episodically, nonetheless performing adequately. His last class had no final examination but required a paper. He planned to write this paper in the form of a play involving a dialogue between two thinkers from different times and cultures. His professor was very excited about this idea, but Mr. A kept postponing the task until he was forced to extend his schooling by a year. His other major interest during this time involved growing and photographing flowers.

Mr. A was born and raised in a large city. His father had been very successful in commercial real estate. His mother, after raising her children, used the substantial real estate holdings she inherited from her father to set up a business to manage them. Most of the money was placed in a trust for the patient and his siblings. His mother had total financial control of the trusts and doled out the proceeds to the children as they needed them. There was no family history of any psychiatric disorders.

The patient described his mother as very loving and caring but to the point of being intrusive and controlling. For example, the mother arranged the initial treatment but then was angry that the psychiatrist had not called her regularly to report on her adult son's progress. She was also critical of various aspects of the treatment as reported to her by her son. The patient's two older siblings had attended prestigious colleges and graduate schools but had returned home to work in the mother's real estate management company. The 30-year-old sister was living in the parents' home. The 35-year-old brother had lived at home for a time but then moved out to a location a few blocks away. There was a younger brother, still in college, who also smoked marijuana excessively. He tried to minimize the patient's problems to the family and tried to protect the patient, who desperately had not wanted to return home. Of note is that none of the children were married, although the two older ones had each had a couple of serious relationships.

The children seemed to regard the mother with affectionate amusement and bemusement. The father was seen as a very caring but undemonstrative man who put much energy into keeping the mother from becoming too upset and encouraged the children to do the same. The children often wanted to provoke the mother for her judgmental, detail-oriented intrusiveness. The father discouraged them but occasionally found their provocations amusing.

The family viewed itself as very close, with strong values oriented toward community service and family loyalty. The family belonged to a religious community but expressed their involvement primarily in social service and social action volunteer work, accompanied by very generous financial contributions.

The patient had been a very successful debater in high school and recalled his development as very positive but provided few details. He tended to place himself in the role of the outsider, an observer of humanity, which he saw as consonant with the role of a writer. He was proud to have bipolar I disorder and tried to regulate his medications so that he would be hypomanic much of the time, seeing this as enhancing his creativity. He viewed his use of marijuana in the same vein. One of the most distressing aspects to him of his depressive episodes was that marijuana no longer created a feeling of well-being but made him feel worse. His current depressive episode involved no neurovegetative symptoms. Rather, he presented as flat, numb, apathetic, ashamed, and anhedonic. He was particularly ashamed of being back in his hometown and of living with his parents.

The patient ostensibly understood and accepted his illness well and had read much about it. However, the family had responded to the information "with proper treatment, bipolars can live normal lives," meaning that the information should be kept secret so that he should be treated normally. Mr. A, on the other hand, was very open with friends at graduate school about his illness and his pride in it, and the creativity he associated with it.

The patient had two longstanding recurrent dreams. One involved him flying. The narrative line varied, but the flying theme recurred. Often, he had other magical powers in his dreams, such as the ability to heal, not be killed by bullets, to save the world or some group of people from mortal danger, and so on. The other recurrent dream was of a hotel lobby. These dreams regularly began with him entering a hotel lobby to meet a group of people, accompanied by a feeling of dread (Table 6.3–1).

ADOLF MEYER

Adolf Meyer (1866–1950) immigrated to the United States after training as a neuropathologist in Switzerland (Fig. 6.3–1). Uninterested in metapsychology, he espoused a commonsense psychobiological approach to understanding mental disorders, emphasizing the interrelationship of symptoms and individual psychological and biologic functioning. His approach to the study of personality was biographical; he attempted to bring psychiatric patients and their treatment out of isolated state hospitals and into communities and was also a strong advocate of social action for mental health. He began his career as a clinically oriented state hospital pathologist, becoming the second head of the Pathological Institute (later, the New York Psychiatric Institute), and initiating its affiliation with the Columbia College of Physicians and Surgeons.

He later became the president of the American Psychiatric Association and had a 32-year tenure as chair of psychiatry at Johns Hopkins. His major social contribution was helping to found the National Committee on Mental Hygiene.

Psychobiology

Despite his background as a neuropathologist, which was common among European psychiatrists of his generation, Meyer strongly opposed the Kraepelinian view of mental illness as having a predetermined course based on phenomenologically identified syndromes. Instead, he believed that individuals' habitual reaction patterns made them more susceptible to specific types of breakdown. Meyer used ***biographical study*** and strongly encouraged psychiatrists to take a thorough, detailed life history of the patient to understand each individual's reaction patterns. He saw development as lifelong, thus viewing the data from adolescence onward as equal in importance compared with data from childhood in understanding the patient's narrative.

Table 6.3–1.
Techniques and Terminology

Meyer	Biographical study approach
	Distributive analysis and distributive synthesis
	Focus on patient assets
	Habit training
Adler	Individual psychology
	Inferiority toward mastery; “inferiority complex”
	Birth order
	Dynamism (future directed, goal oriented)
	Removing blocks to living productively in the real world
	Reframing
	Paradoxical communication
Jung	Complexes
	Archetypes
	Projective/introjective processes
	Persona, shadow, anima, and animus
	Typology (introversion–extroversion, sensation–intuition, thinking–feeling)
Alexander	Psychosomatic medicine
	Corrective emotional experience
	Controversial attempts to shorten/manipulate psychodynamic therapy
Reich	Ego psychology
	Character armor and personality types
	Bioenergetics
Horney	Gender, culture, and personality traits
	Theory of neurosis, character neuroses, and neurotic trends
	Alienation
Fromm	Importance of historical and social context for human behavior
	Marxist view of character types

Sullivan	Therapeutic communities
	Definition of personality and emphasis on interpersonal relationships
	Cognitive modes: prototaxic, parataxic, syntactic
	Social development model
	Interpersonal psychotherapy
Berne	“Strokes” as primary motivators
Chodorow	Feminist psychoanalysis
	Gender identity development
	Parent child relationship and “mothering”

He observed reaction patterns, attempted to predict the conditions under which they might occur, and tested and validated methods for their modification. He acknowledged the contributions of Freud and Jung but believed they were too narrow. A thorough pragmatist, he preferred common sense to metapsychological constructs as the means to understand and deal with psychopathology.

Theories of Personality and Psychopathology

Meyer believed human beings possess a fundamental tendency toward integration, and multiple biologic, social, and psychological forces contribute to personality development. The vulnerable person uses poorly planned, ill-suited means of adaptation. Meyer used the biographical approach as a practical guide to elicit information about personality development, organize the information, and re-evaluate the information obtained under different circumstances. His clinical examination assessed each patient’s life history; physical, neurologic, genetic, and social status; and the relationship between those factors and personality factors. A diagnosis and an individual treatment plan were based on this assessment.

FIGURE 6.3–1. Adolf Meyer. (Courtesy of National Library of Medicine, Bethesda, M.D.)

Treatment

The aim of psychobiological therapy was to help individuals make the best possible adaptation to changing environmental circumstances. It began with the development of a collaborative relationship. Out of this collaborative relationship came ***distributive analysis***, an examination of the factors in patients' lives that contributed to their adjustment or lack thereof, and concluded with ***distributive synthesis***, helping patients to understand themselves and to develop better coping skills. The first step in distributive analysis is the patient's own exposition of the presenting problem. Assets and liabilities are then determined by eliciting the life history in terms of the memories that are immediately available and those that are later fleshed out by reconstructing past experiences.

Treatment is initiated by ***focusing on patients' assets***. It involves psychological, chemical, physical, and environmental measures as needed. In more severe cases, attention is paid first to patients' sleep habits, nutrition, and daily routines because these must be normalized before psychological work can be done. Patients are helped to describe their difficulties in detail. In addition to eliciting complaints or worries, patients are asked what eases or worsens their complaints and what significance they attach to their symptoms and concerns. In doing this, the therapist attempts to use the patient's own language and concepts to communicate suggestions and advice.

Meyer did not pay attention to unconscious mechanisms but focused on patients' functioning in reality. Both present-day and long-term adaptive patterns are considered. Therapeutic sessions proceeded from immediate, obvious problems in the present to longer-term issues and historical data. With guidance, patients investigate their own personality problems, ascertain the origin of their conflicts, and work to develop more useful behavior patterns. Meyer called this ***habit training***, a term he may or may not have borrowed from a behaviorist tradition. When unhealthy adaptive patterns are modified, proper adjustment and personal satisfaction result.

Meyerian Treatment of Mr. A

Meyerians would focus first on the adequate treatment of Mr. A's mental illness. Controlling biologic forces that might disrupt his life is always a primary goal. Because he is still dependent on his parents, they are included in the treatment plan and might be seen separately by a social worker. Both Mr. A and his parents are told that failure to control the symptoms of his mental illness could cost him his life and any satisfaction that he might derive from it. Mr. A's mood swings are stabilized on appropriate medication, and he is observed closely for restoration of normal sleeping and eating habits. With our modern knowledge of neurobiology, the vulnerability of Mr. A's dopamine reward system to addiction would be another biologic force to be dealt with. He is asked to discontinue his habit of marijuana use for this reason, but also because of its tendency to aggravate the symptoms of his mental illness. Random urine screening might be recommended. Mr. A is helped to develop a daily schedule, including time for work, social interaction, and recreation. He is not encouraged to return to school because of his tendency to use school as an escape from responsibility. He is encouraged to develop his photography as a hobby after a period of stable work performance. Later, he would begin the distributive analysis phase of his treatment and would be asked to reflect on the impact of his bipolar I disorder and his avoidance of responsibility in his life. In the distributive synthesis phase of treatment, he is helped to realize that his avoidance of responsibility keeps him from achieving independence and the pleasure of attaining any realistic goal. He is asked to develop a plan for achieving both appropriate independence and for remaining within the family structure. Mr. A's parents are seen periodically for a progress report and to urge them to push Mr. A toward appropriate self-care, toward making use of his own resources. They might be asked to place Mr. A on an allowance and to hold him to it strictly to reinforce his accountability for his actions. Over time, his parents are asked to slowly withdraw financial support and to give Mr. A more independence. They might be asked to place his inheritance in a trust designed so that he could not impulsively misspend it.

ALFRED ADLER

Alfred Adler (1870–1937) was born in Vienna, Austria, and spent most of his life there (Fig. 6.3–2). A general physician, he became one of the original four members of Freud's circle in 1902. However, Adler never accepted the primacy of the libido theory, the sexual origin of neurosis, or the importance of infantile wishes. In 1911, he resigned as president of the Vienna Psychoanalytic Society and continued the development of his own socially and interpersonally focused theory of development. He posited a striving for self-esteem through overcoming a sense of inferiority, which he saw as an inevitable force in the human condition as a result of its extended childhood. He equated psychological health with constructive social engagement, developing a system that he called ***individual psychology***, which is still vigorous in many countries. His major social contribution was the establishment of child guidance centers in Vienna that served as a model for the rest of the world.

Dr Alfred Adler

FIGURE 6.3–2. Alfred Adler (print includes signature). (Bettmann/ Contributor via Getty Images.)

Personality Theory

Adler saw individuals as unique, unified biologic entities whose psychological processes fit together into an individual lifestyle. He also postulated a principle of ***dynamism***, which in every individual is future directed and moves toward a goal. Once the goal is established, the psychic apparatus shapes itself toward the attainment of that goal. Life goals are chosen and are thus subject to change. Changes require modification of memories, dreams, and perceptions to fit the accomplishment of the new goal. Adler also emphasized the interface between individuals and their social environment and the primacy of action in the real world over fantasy. Community mindedness, acceptance of the need to conform to the legitimate demands of society, is an important precept, but Adler also recognized a dialectic that occurs between individuals and their interpersonal environment, each constantly reacting to and shaping the other. Thus, Adler anticipated some of the modifications of Freud's theories introduced by Heinz Hartmann as well as some of Sullivan's thinking.

Normal Personality and Adaptation. The cornerstone of Adler's personality theory is the concept of ***moving from a sense of inferiority to a sense of mastery***. Early in life, everyone has a sense of inferiority resulting from realistic comparison with adults' size and abilities. Moving from this sense of inferiority to a sense of adequacy is the most important motivation in life. Thus, the ideal person strives for superiority and does so through high social engagement; the emotionally handicapped person continues to feel inferior and reinforces that position through a lack of striving and social interest.

There are many obstacles to the development of self-esteem and social interest. Prominent among them are poorly developed or "inferior" organs or systems (such as poor eyesight or poor eye–hand coordination), childhood diseases, pampering, and neglect. Physical disabilities and childhood diseases may promote self-centeredness and loss of social interest; ***birth order*** is another factor. According to Adler, first-born children, having lost their position as the only child, tend not to share and become conservative. Later, children are more open to change and become social activists. The youngest children feel secure because they have *never* been displaced. Adler may have been the first to anticipate recent psychological research on the importance of birth order in human behavior. We acknowledge our indebtedness to him whenever we use the term “inferiority complex.” Adler was also the first theoretician to place mastery and self-esteem at the center of personality development.

Theory of Psychopathology

Adler believed emotional disorders result from “mistaken lifestyles” that are subject to change by will and by self-understanding. Individuals subject to emotional disorders have false ideas about themselves and the world and inappropriate goals that lead them away from constructive social interest. Individuals with a pampered lifestyle, for example, expect and demand support from others, avoid responsibility, and blame others for their failures, but they also feel incompetent and insecure because their well-being depends on pressing others into service. If life poses no challenge, a mistaken lifestyle may have no consequences. When a mistaken lifestyle is ineffective, symptoms develop that protect self-esteem while helping the individual to avoid dealing realistically with the problem being confronted. The difference between neurosis and psychosis is that neurotic individuals maintain social interest but are blocked from life goals by symptoms, whereas psychotic individuals lose social interest and retreat into their own world.

Psychotherapy

Because his theory emphasized the mismatch of lifestyles with the demands of the real world, Adler focused on ***blocks to living productively in the real world***, not on exploring unconscious conflict. His aim was to point out mistaken self-views and mistaken views of the world and then, by mobilizing will, make the needed changes, including a change in life goals.

Therapeutic Process. Starting with three sessions per week and tapering off to one per week, a positive relationship with patients is established and used to lead patients to awareness of their lifestyle, how it is discordant with the demands of social reality, and ways in which it may be reoriented. Instead of striving for goals of no social value that falsely increase self-esteem, patients are pushed to work toward ameliorating their situation. Having become aware of the obstacles they have placed in their own path and the consequences of these self-defeating behaviors, they are now helped to develop constructive interests in themselves and others. As they become less self-engrossed, they find themselves better accepted by others, which reinforces their constructive efforts. People who have dedicated themselves to symbolically defeating others learn to cooperate and advance toward useful goals. Any endeavor in which patients can develop real competence is encouraged, whether social, vocational, artistic, or musical.

Patients are encouraged to address the concrete obstacles to developing a useful lifestyle, including reading instruction for slow readers or contact lenses for people who are self-conscious about their appearance. Early recollections, birth order, dreams, daydreams, and present-day interactions are all used to help patients see the inappropriateness or falseness of their ideas and life goals. Actual life events or memories of events are less important than individuals' reactions to those events or memories. Because memories are likely to be retrospective falsifications justifying an erroneous lifestyle, there is little need to verify them. There is also no need to look for latent content in dreams; they are merely an expression of present-day concerns. Nor is it necessary that therapists' interpretations be correct because they need only to help patients build a useful conception of themselves and the world. This perspective anticipated what has come to be called the *hermeneutic approach* to psychotherapy.

Several of Adler's techniques, including reframing and paradoxical communication, now enjoy wide popularity. ***Reframing*** is viewing the same data from a different point of view. Indecision, for example, was reframed from a product of mixed feelings to a wish to maintain the status quo. Failure to act keeps everything the same, which is the self-fulfilling prophecy of the discouraged person. After this reframing statement, patients are pushed to act constructively. ***Paradoxical communication*** is instructing patients to do the opposite of what the therapist wishes them to do. In dealing with an indecisive person, for example, Adler might caution against doing anything rash. Adler also paid attention to the impact of his patients on their environment and recognized that individuals do much to create their own interpersonal worlds. In response to complaints about being treated unfairly by others, Adler asked patients how they dealt with the people about whom they complained. Above all, Adler treated his patients as rational and as able to learn more productive ways of living. In his emphasis on practical, constructive solutions, misconstrued goals, and misperceived views of the world and the self, Adler also anticipated important elements of cognitive therapy.

Adlerian View of Mr. A

As seen from the Adlerian point of view, Mr. A has developed a mistaken lifestyle and an inappropriate life goal. He maintains himself in fantasy as a writer while failing at the accomplishments that would enable him to become a writer. Thus, he has been attempting to make the normal step of moving from inferiority to mastery in fantasy instead of through realistic achievement. Blocks to his development include pampering and his concomitant denial and abuse of his bipolar I disorder, the latter representing his organ inferiority. He lost the social interest he had earlier in life and became extremely self-centered, unconcerned with others or with the consequences of his actions. He uses drugs and hypomania to avoid the pain of defeat.

An Adlerian therapist encourages Mr. A to develop a realistic self-view. He has a mental illness that requires lifelong treatment. Grandiose dreams and intoxication with drugs cannot substitute for accomplishments in the real world and always lead to defeat. He is asked to set and strive to accomplish small, realistic goals for himself, such as holding a steady job while enjoying photography as a hobby. His mental illness is reframed as a challenge to his creativity and his use of marijuana as an obstacle to mobilizing his creativity. He might initially be encouraged to accept his dependency on his family and later, as he stabilizes, to reduce his dependency on his family as a means to heighten his self-esteem and to make a transition into adulthood. He is encouraged to join the Depression and Bipolar Support Alliance or other available support and educational groups as a means to better understand and accept his illness, to develop a social conscience, and to stimulate his altruism. His dream about flying is interpreted as his wish to achieve mastery; his dream about the hotel lobby is recast as awareness that he has been trying to substitute fantasy for reality.

CARL GUSTAV JUNG

Carl Gustav Jung (1875–1961) was a lifelong resident of Switzerland (Fig. 6.3–3). He trained in psychiatry under Eugen Bleuler at the Burgholzli Mental Hospital in Zurich and was strongly involved with Freud and the psychoanalytic movement from 1906 to 1914 when he resigned as president of the International Psychoanalytic Association. He was an important figure in connecting psychoanalysis with clinical psychiatry. After a period where he experienced psychotic symptoms but made use of them as a spur to creative thinking, which lasted from 1914 to 1918, Jung became an advocate of active introspection as the means to intrapsychic change. This episode and Jung’s subsequent interpretation of it, as well as that of his disciples, form the focus of much of the controversy about him and his ideas. Although Jung rejected Freud’s notion of libido as sexual energy and the Oedipus complex as a universal developmental stage, he believed not only in the unconscious mind but in a shared racial and species unconscious. This interest of Jung’s is the source of another controversy involving Jung’s relationship to the Nazi establishment. Jung, an intuitive introvert, was not interested in the practical aspects of living in the world; his focus was instead on individuation through becoming aware of the unconscious. His theories have particular attractiveness to clinicians and nonclinicians interested in spirituality, creativity, and mystical experience.

Personality Theory

Jung developed an elaborate metapsychology that was every bit as detailed and formalized as Freud's. His theories identify most of the important fault lines in classical psychoanalysis. Jung's construct of the psychic apparatus differs from the Freudian structure of the ego, superego, id, and ego ideal (Fig. 6.3–4). Below an outer rim of consciousness is the personal unconscious, which contains the complexes. Contained within the personal unconscious and connected to the complexes are the archetypes, the elements of the self, which in turn connect to the surface of the personality as the ego.

Complexes. ***Complexes*** are groups of unconscious ideas associated with particular emotionally toned events or experiences. Jung inferred them from his early word association studies when he noted that certain words provoked intense reactions or produced less reaction than expected. Complexes are built around genetically determined intrinsic models of the world known as ***archetypes***. Complexes are also reinforced by environmental events and by selective attention or inattention and are thus self-perpetuating. They are endowed with psychic energy from their affective tone: positive, negative, mild, or strong. The more intense the complex is, the greater the emotion, imagery, and tendency to action. Complexes are often stimulated by interactions with others. A father complex can be stimulated by a person who symbolizes a father (such as an older friend) or by a stimulus, such as music or art, that evokes father memories. The complex, formerly dormant in the unconscious, comes to the fore and tends to dominate consciousness and to displace other complexes. This is a very different model of the dynamic unconscious from Freud's, in that the boundary between the conscious and unconscious is far more permeable, and the emphasis is on what in external reality stimulates feelings and thoughts to enter awareness rather than on what forces a complex out of awareness. Similarly, Jung's conceptualization of interpersonal boundaries was far more permeable than Freud's; Jung also placed much more emphasis on nonverbal stimulation (music, art, spiritual life) in this process than did Freud.

Some complexes are more conscious, better developed, and more acceptable to the individual; others are less conscious, poorly developed, and uncomfortable. The latter are projected onto the environment, especially by children, and from this, ***projective*** and ***introjective*** processes evolve. One person may introject and identify with a complex being projected by another person. Thus, therapists may become psychologically infected by their patients. It is also possible to project a complex that is not integrated within oneself onto another person and then develop a relationship with that projected complex. One can envision an interpersonal environment charged with mutual projections available for introjection, thus offering endless potential for mutating perceptions and misperceptions. Thus, for Jung, the psychological boundary between individuals was far less clear than for Freud or Adler. In addition, one can see that Jung was much less concerned with an ultimate, objective, rational reality to be determined and compared with the individual's complexes of projections and introjections. Jung also had a parallel appreciation for the process of projective identification that Melanie Klein was developing at approximately the same time. Working as he did for many years in a long-term sanatorium with very ill patients, Jung clearly became comfortable with blurred interpersonal boundaries. His theory has been criticized for accepting as normative what might be regarded as pathologic models of relationships.

Another important aspect of complexes is their ***bipolarity***, again paralleling Klein's work on splitting. Each complex has a positive and negative pole, such as good father and bad father or rewarding father and punishing father. One pole of a complex can be projected onto another person, who in turn introjects it and acts on it in a relationship. In this way, the theory of complexes is a theory of interpersonal as well as intrapsychic relationships.

In Jungian theory, the ego is also a complex. It serves the same function as the Freudian ego, controlling conscious life and bridging the intrapsychic and external worlds. The other complexes that also make up the psyche may align with or lie in opposition to the ego. Emotionally charged primitive complexes (e.g., the earth mother in a patient ambivalent about motherhood) have a tendency to become autonomous and may, when activated by external stimuli, behave to oppose or control the ego, leading to irrational, impulsive behavior or misperceptions. They appear as images in dreams, as hallucinations, and as separate personalities in dissociative identity disorder. They also appear in séances when mediums bring forth so-called personalities from the dead. For Jung, this phenomenon also explained animism and states of possession.

Jung had a great interest in mystical experience, which Freud saw as the persistence of infantile, magical thinking, primary process, or wish fulfillment. This is another of the clear divisions in their thinking. For Freud and Freudians, the world is a harsh, demanding place that forces one to give up primitive wishes for magical experiences, symbiotic relationships, and intense gratifying emotional moments. For Jung and Jungians, magic is alive and well in the inner world and is to be embraced.

Archetypes. Complexes are connected to structures embedded more deeply in the psychic apparatus, the archetypes. ***Archetypes*** are the inherited capacity to initiate and carry out behaviors typical of all human beings, regardless of race or culture, such as nurturance and aggression. Just as vision cannot develop without visual input during critical physiologic stages, so archetypes require interactional stimulation for their elaboration into complexes. Thus, the human infant’s psyche is not amorphous energy awaiting organization by the environment; it is instead a complex and organized set of potentials whose fulfillment and expression depend on environmental stimuli. There are as many archetypes as there are prototypical human situations. In positing the archetypes based on anthropologic data, Jung was remarkably prescient of the current understanding of the brain’s organization.

The mother complex archetype illustrates the interrelationship of complex and archetype. All humans are born with a poorly formed but relatively clear model of an all-nurturing caretaker, which Jung referred to as the *earth mother archetype.* The mother complex emerges from this based on experiences with mothers or mother surrogates: their attitudes, personalities, and relationship to the particular individual. The mother archetype is found in dreams or fantasies, often as a huge woman or an animal with many breasts. The motif of a many-breasted animal, found in many cultures, is that of unlimited nurturance.

Unconscious. The Jungian unconscious has two layers: the more superficial being the personal unconscious and the deeper layer the collective unconscious. The complexes exist in the personal unconscious, the archetypes in the collective unconscious or *objective psyche.* The *personal unconscious* is the equivalent of the Freudian unconscious, a repository of individual memories that have been repressed. The *collective unconscious* is the residue of what has been learned in humankind's evolution and ancestral past, much as human deoxyribonucleic acid (DNA) is an aggregate of the past. In this portion of the psyche reside instincts, the potential for creativity, and the spiritual heritage of humankind. The potent synthesis of Darwinian natural selection theories with Mendelian genetics, which has had such a profound impact on all of biology, occurred in the 1920s. It is not clear whether Jung was aware of this intellectual thrust, but his understanding of the collective unconscious and of the archetypes is remarkably consonant in form, if not in detail, with the modern understanding of hereditary and developmental neurobiology as applied by cognitive science.

The psyche, like all other living systems, attempts to stay in balance. Jung's term for homeostasis in the relationship of conscious to unconscious life is the *law of compensation*. For any conscious attitude or experience that is overly intense, there is an unconscious compensation. A person experiencing neglect might fantasize or dream about a huge, many-breasted mother. When interpreting dreams, Jung asked himself for what conscious attitude the dream compensated.

Personality Structure. At the center of the conscious personality is the complex called the *ego*. Several universal complexes attend to the ego. The ***persona***, or public personality, mediates between the ego and the real world. The ***shadow***, a reverse image of the persona, contains traits that are unacceptable to the persona, whether positive or negative. A brave persona, for example, has its fearful shadow. The archetype of the shadow is the enemy or feared intruder. The ***anima*** is a residue of all the experiences of woman in a man’s psychic heritage; the ***animus***, the residue of all the experiences of man in a woman’s psychic heritage. The anima or animus connects the ego to the inner world of the psyche and is projected onto others in day-to-day or intimate relationships. When connected with the shadow, a man, for example, might see attributes of woman as undesirable and might experience guilt encountering such qualities in himself.

SELF. The *self* is the archetype of the ego; it is the innate potential for wholeness, an unconscious ordering principle directing overall psychic life that gives rise to the ego, which compromises with and is partly shaped by external reality. In Jungian metapsychology, the unconscious gives rise to integration, order, and individuation. The self appears from the unconscious in dreams, fantasies, and altered states of consciousness to give direction. In the first half of life, the ego attempts to identify with the self and to appropriate the power of the self in the service of the ego’s growth and differentiation. During this time, the ego may become inflated with an unrealistic sense of power. If it is cut off from the self, there may be a sense of alienation and depression.

INDIVIDUATION. In the second half of life, the ego begins to attend more to the self than to the conscious realm of life. Jung called this developmental process *individuation,* the drive for individuals to become unique and to fulfill the spiritual propensities common to all humanity. Often, this process requires withdrawing from earlier identities and conventional definitions of success and seeking new paths. This change often has the paradoxical effect of leading to broader and more mature relationships in addition to greater creativity.

PSYCHOLOGICAL TYPES. Jung's theory of psychological types has three axes (Fig. 6.3–5). The *extroversion–introversion* polarity refers to the two basic types of object relatedness. Extroverts are oriented to others and to the world of consciousness. Their energy flows outward first, then inward. Introverts are oriented to their inner world, their energy flowing first inward and then to outer reality. Introverts might therefore be seen as selfish and unadaptable because they attend first to their inner world and then determine how the outer world can fit them. Extreme extroverts, on the other hand, can seem insensitive to themselves and to the inner lives of others.

The *sensation–intuition* polarity concerns perception. The sensation type comes to understand a situation by assembling the details; the intuitive type grasps the overall situation before attempting to assimilate its parts. The sensation type sees the trees first; the intuitive type sees the forest first.

The *thinking–feeling* polarity deals with information processing and judgment. In the *thinking* mode, data are evaluated according to logical principles. *Feeling*, at the opposite pole, is making judgments through nonlogical processes having to do with values and understanding relationships. In social relationships, the thinking type deals with people according to their social rank or according to the tradition of etiquette; a feeling type deals with others in terms of their present social relationship or perceived emotional state.

Each individual has a preferred mode on each of these three dimensions. By placing an individual on each of the three axes indicated in Figure 6.3–6, each individual can be identified as a type. An extroverted–sensation–thinking type is oriented to the real world, tends to perceive external details, and organizes them into a logical structure. An introverted–intuition–feeling type is self-oriented, grasps situations as a whole, and is sensitive to their emotional implications.

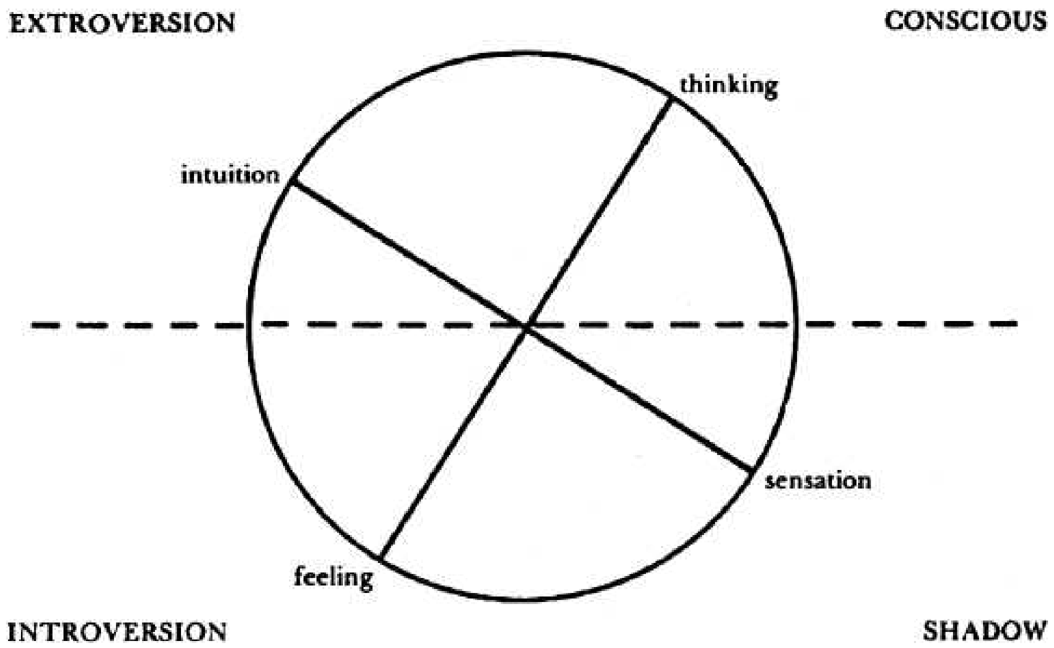

FIGURE 6.3–6. The three personality axes: extroversion–introversion, thinking–feeling, and intuition–sensation. (Reprinted with permission from Princeton University Press. Stevens A. On Jung, Updated Edition, 1999.)

Everyone's psyche contains all of the types. However, each person has a superior set of types that are evolved from early life and that are shaped strongly by temperamental factors. In the second half of life, adults who continue the process of individuation attempt to integrate or broaden and deepen their understanding of their inferior functions. The Myers–Briggs Type Indicator, a simple paper-and-pencil test consisting of approximately 40 questions, reliably places individuals on these dimensions. It has become a very popular instrument among psychology, management consulting, counseling, and self-improvement organizations for quickly identifying the qualities of individual participants. This typology may be the most widely known and accepted aspect of Jung's theories, although it is often used independently of its original context.

Therapeutic Process

Jung suggested that therapy begin with four visits per week and then be spaced out to one or two per week. Present-day Jungian practitioners may work with their analysands once a week, face to face. Jung placed great emphasis on the human relationship between analyst and analysand and noted that both parties change in the course of analysis. He defined *transference* as the patient's attempt to develop psychological rapport with the doctor and held that without rapport and object relationship, the technical operations of the analyst were of no value.

With its emphasis on reintegration, symbolism, and dreams, Jungian analysis seems well suited to help educated people deal with the developmental problems of midlife. Having achieved a professional identity, material success, and established a firm family role, they often begin to ask, “Who is the real me?” “What is most meaningful to me?” and “What is my relationship to humankind and human history?” However, the complicated, often blurred intrapsychic relationships described and the interest in mystical experience with its potential shading into magical thinking mean that Jungian clinicians must be careful about the risk of blurring the therapeutic boundaries. The break between Freud and Jung, which had for decades been ascribed to Freud’s rigidity and authoritarianism, now appears to have had a contribution from Jung: Freud disapproved of a complicated, dependent relationship Jung is believed to have had with a former patient.

Jungian View of Mr. A

Jungians see Mr. A’s symptoms of bipolar I disorder and use of marijuana as having unleashed conflicting archetypes, all attacking the ego complex he had grown up with. This could be seen as an opportunity for Mr. A to claim a fuller definition of the self. Mr. A’s aspirations to be a great writer are taken as potentially healthy, and even the content of his psychotic and substance-induced states is analyzed so as to incorporate their meanings into his ego complex. Mr. A’s previous psychological type is described as extroverted–sensation–thinking—an observer of life but not a full participant. The type emerging in his psychotic and intoxicated states is described as introverted–feeling–intuitive—the self-absorbed, self-experiencing lover of beauty and ideas. The dreams about flying suggest an expression of the hero archetype; the anxiety dream suggests some emergence of his shadow in association with his aspirations to be a writer. His love of flowers and creativity during his periods of psychosis and intoxication suggests that the shadow is connected to his anima.

The task of therapy is to assist Mr. A in accepting these alien parts of himself and integrating them into his ego complex. Relatively less emphasis is placed on education or specific treatment of his bipolar I disorder, except insofar as it prevented a good therapeutic alliance. His fantasies, dreams, and psychotic experiences are investigated, discussed, and analyzed in terms of the psychological functions used and the archetypes expressed. His interpersonal issues with his family are seen primarily as projections by him of other unacceptable archetypes that need identification, analysis, acceptance, and integration. For example, his relationship with his mother is seen as a projection and fear of the earth mother archetype. The overall goal is to harness the unleashed unconscious material to allow Mr. A to pursue his ambitious and creative goals.

FRANZ ALEXANDER

Franz Alexander (1891–1964) was one of the second generation of psychoanalysts. He was born in Budapest and attended medical school there, graduating in 1912 (Fig. 6.3–7). He conducted research at the Institute for Experimental Pathology in bacteriology until World War I, when he practiced clinical microbiology on the Italian front, primarily combating malaria. After the war, he joined the Department of Psychiatry at the University of Budapest Medical School as a brain researcher. This led to an encounter with Freud's work, and, in 1919, he became the first student of the Berlin Psychoanalytic Institute. In 1930, Alexander became a visiting professor of psychoanalysis at the University of Chicago and, in 1932, founded the Chicago Psychoanalytic Institute. He established the institute independent of the psychoanalytic societies, leading the Chicago Institute to be one of the more creative sources of psychoanalytic thought. During the same time, he became interested in what he called psychosomatic illnesses (today referred to as somatic symptoms and disorders), helping to found the journal *Psychosomatic Medicine.* A guiding principle of his work was to make psychoanalysis an integral part of medicine.

FIGURE 6.3–7. Franz Alexander. (Courtesy of Franz Alexander.)

In 1946, Alexander became a professor of psychoanalysis at the University of Southern California, where he continued his work on ***psychosomatic medicine*** and became interested in the interface of learning theory, the psychophysiology of stress, and psychoanalysis.

Theory of Personality

Alexander did not develop a unique overarching theory of personality; his contribution was his application of psychoanalytic thought to pathophysiologic processes. In this, he laid the groundwork for the burgeoning fields of psychosomatic medicine, behavioral medicine, and psychophysiology. Alexander created the basis for the biopsychosocial model and studied the mind and body at a time when American psychiatry, despite Freud's original ideas, had become purely psychological in its orientation. In studying and treating many patients with serious physical illnesses, he was also forced to consider creative modifications of therapeutic techniques.

Alexander and his group began by intensively studying, by means of clinical interviews, patients who had one of seven illnesses that had been identified by general practitioners as having strong psychological components: peptic ulcer disease, ulcerative colitis, essential hypertension, Graves disease, neurodermatitis, rheumatoid arthritis (RA), and bronchial asthma. Out of these clinical studies emerged the specificity hypothesis, which proposed that certain illnesses are the product of a complex interaction of specific constitutional predispositions, specific unconscious conflicts, and specific types of stressors that activate such conflicts. The group then tested these hypotheses in a series of clinical studies of patient populations. The independent variable was usually the ability of skilled clinicians to predict a patient's illness from disguised case reports.

In the field of psychotherapy, Alexander was one of many who sought to shorten the analytical process. He hypothesized that intellectual insight was not the central curative factor in therapy, a radical and revolutionary proposal at the time. Rather, he emphasized the role of ***corrective emotional experience*** or the exposure to past conflicts or emotions in the safety of the therapeutic setting**.** The corrective emotional experience allowed patients to re-experience old conflicts and painful emotions while creating a new outcome within the context of a more positive emotional experience with the analyst. During the session, patients may draw on strength and support from the therapist, which provides an opportunity for processing the emotion in a healthier way. Alexander began to experiment with variations in technique that might facilitate such experiences, including using transference to serve as a proxy parent and respond to patients in ways that correct the pathologic patterns of parental responses they received as children. Consideration of a corrective emotional experience as a core feature to treatment, his most controversial stand, nearly ruptured his relations with the psychoanalytic movement.

Theory of Psychopathology

The seven diseases that Alexander studied (peptic ulcer disease, ulcerative colitis, essential hypertension, Graves disease, neurodermatitis, RA, and bronchial asthma) were studied to identify the single, specific core conflict that, in interaction with constitutional predispositions and in the circumstance of a particular stressor, would activate the disease.

The core conflict identified in peptic ulcer disease was hyperindependence as a defense against unacceptable dependency needs. The stressor that results in an acute attack can be any situation that demands that the individual openly acknowledge or ask that dependency needs be met. Ordinarily, patients use dominance and control to intimidate others into meeting their dependency needs. This particular illness model received confirmatory evidence from a study of army inductees in whom psychological profiles as described by Alexander, in combination with measurements of serum pepsinogen, were successful in predicting the development of duodenal ulcers. It is not clear what the impact of the recent recognition of a specific pathogen means for this particular hypothesis. Perhaps the identified pathogen, *Helicobacter pylori*, is the constitutional factor that had previously been believed to be serum pepsinogen concentration, or perhaps Alexander's hypothesis only applies to some subgroup of patients with duodenal ulcers. More recent research suggests a number of correlates of peptic ulcer in addition to *Helicobacter pylori,* including use of pain-relieving medicine (particularly nonsteroidal anti-inflammatory drugs or NSAIDs), heavy alcohol consumption, use of nicotine products, low socioeconomic status, and different types of stressors such as physical, psychological, and occupational. Evidence supports the impact of stressors on ulcers, but not specifically the effects of unconscious conflicts or defenses.

Alexander's theory of ulcerative colitis also implicated dependency conflicts; however, rage at unmet needs was seen as the defining feature. This rage provokes guilt and the urge to make restitution toward the object of anger by means of gifts of achievements and successes. The model here is clearly the angry child seeking to placate a parent by means of performance. The precipitating event for reactivation of the illness is the perception that the efforts at placation will be unsuccessful. Alexander claimed that this resulted in excess parasympathetic activity, leading to diarrhea. Current research on the etiology of ulcerative colitis remains inconclusive, with some research suggestive of little to no connection between psychiatric diagnoses or stressful life events and disease status and severity. Other research indicates a moderate correlation between depression and Crohn disease, but not ulcerative colitis. However, evidence for Alexander's theory of dependency conflicts causing ulcerative colitis has not been supported or confirmed.

Alexander's hypothesis about essential hypertension focused on inhibited anger and suspiciousness in an outwardly compliant, cooperative individual. A hypertensive patient often goes for long periods with blood pressure under good control and then, seemingly inexplicably, experiences a dramatic increase in blood pressure. Alexander attributed these episodes to incidents when the chronic anger is exacerbated, and intense defenses must be used, causing chronic sympathetic fight-or-flight activation. Several psychophysiological studies have suggested that this theory has some validity, at least in terms of short-term changes in the blood pressure of a subset of people with hypertension. Individuals with labile mood and hypertension appear to fit this model best. This theory is not generalizable to all cases of hypertension and does not account for other factors identified in current literature. Modern-day views of hypertension focus on various causative factors such as genetics, behavior, and psychosocial stress. Evidence supports the impact of chronic psychosocial stress on the risk of developing high blood pressure over time. Factors such as socioeconomic status, racial discrimination, sex, and stress in occupation and relationships are also being studied as potential correlates to the development and exacerbation of hypertension.

The proposed specific conflict for RA postulates rebellion against overprotective parents. A compromise formation in which the conflict is discharged via physical activity, especially sports, works for a time, but the anger eventually is expressed in self-sacrifice designed to control others. Failure of this pattern results in increased ambivalent tension, directly expressed via muscular contractions that lead to joint degeneration. Alexander's specific theory about RA is not supported by current research. However, psychological stress, particularly adverse childhood events and chronic distress, can exacerbate symptoms of RA and increases the risk of developing arthritis.

Alexander proposed that the wheeze of bronchial asthma represented a symbolic cry. The specific conflict, according to him, was the wish for protection versus the fear of envelopment. This conflict leads to sensitization to separation issues, which become the events that provoke the suppressed cry of the asthma attack. In recent years, it has become clear that the population with asthma is far more heterogeneous both psychologically and physiologically (in terms of vulnerability to allergens) than was recognized in Alexander’s time, and that immunologic variants play the primary role in the illness etiology and not unconscious wishes and fears. The role of a vicious physiologic–psychological cycle in which asthma stimulates panic, which in turn triggers pathologic pulmonary psychophysiological responses, has been a focus of more recent research.

Although the role of stress and anxiety in neurodermatitis remains widely accepted by clinicians, the specific conflict proposed by Alexander, that early deprivation leads to wishes for closeness that are opposed by a fear of it, is no longer accepted. Finally, Graves disease (thyrotoxicosis) is no longer widely accepted as a purely somatic disorder. Alexander’s hypothesis was that premature responsibility led to a martyr-like denial of dependency. Although the exact cause remains unknown, genetic and environmental risk factors play a role, and physical and psychological stress can precede the onset of the disease.

Treatment

The specificity hypothesis led Alexander to focus his psychotherapeutic efforts in a way that other analysts of his time did not. He reasoned that if he could help patients to resolve their core-specific conflict without necessarily addressing other parts of their personality structure, the medical illness would improve. Indeed, he published numerous case studies suggesting just this kind of success. In addition, he was among the first to question the value of intellectual insight as to the curative agent in psychotherapy. He proposed that a corrective emotional experience is the central agent of change. A corrective emotional experience involved disconfirmation within the transference relationship of previous assumptions and projections.

Thus, Alexander felt justified in introducing a variety of techniques that would initially induce and heighten the emotional experience of the transference and, subsequently, challenge the underlying unconscious assumptions. These techniques included manipulating the frequency and length of sessions, making direct suggestions about the patient’s life, self-conscious alteration of the therapist’s behavior according to the patient’s conflict, and behavior therapy techniques. In many ways, this was the most controversial aspect of Alexander’s work. Serious questions about the validity of his suppositions and the ethics of his “manipulative stance” were raised. He was impatient with the slow, methodical process of convincing his colleagues; his intellectual energy led him to embark on ever-newer experiments while other analysts were still struggling to digest his previous suggestions. Yet today, few quarrel with the concept that emotional learning is at least as important as intellectual insight in psychotherapeutic success. Alexander's efforts to modify and shorten the analytical process have come closer to the norm in psychiatric practice than classic analysis. Indeed, his emphasis on a specific focal conflict that could be addressed in brief therapy by modifying techniques anticipated the later work of Peter Sifneos, David Malan, Habib Davanloo, James Mann, and Gerald Klerman, and Myrna Weissman, who systematically developed broad-based models of brief psychodynamic psychotherapy.

Ironically, although Alexander's therapeutic innovations seem prescient today, his specificity hypothesis, which was far less controversial, seems simplistic, naive, and forced. He did not have available the sense of how complicated illness causation truly is. The dominant model of the time was infectious disease: One organism, one illness. In addition, the complexity of social phenomena and stressors was unknown in his time. Yet, Alexander was the first to postulate a multicausal etiology for disease: a specific constitutional defect, a specific conflict, and a specific stressor, all necessary for a disease to occur. He was also the first to study mind–body interactions in a systematic way.

Alexander's View of Mr. A

In the absence of a clear somatic disorder, Alexander would have had little to say specifically about Mr. A's dynamics. However, like any good dynamically oriented psychotherapist, he would have readily recognized Mr. A's core conflict about dependence–independence. Mr. A would be understood as rebelling against his mother's nurturing control, although secretly desiring to continue basking in it. He has serendipitously found that illicit drugs and his mental illness can be harnessed such that his mother has to rescue him and take over while he avoids becoming aware of the conflict. Alexander's unique contribution to Mr. A's case would be to propose that he could be treated with 40 or fewer sessions, focusing exclusively on this conflict (and ignoring others such as oedipal components and issues with his father). Further, Alexander's agenda would be to structure the therapeutic relationship to intensify Mr. A's experiencing this conflict. He might do this by taking a somewhat intrusive, directive stance, thus creating the opportunity for a rapidly intense transference around this issue. Alexander might then spread out the sessions to elicit expression of the patient's yearning for that control. The key therapeutic effort is then to respond constructively to attempts by Mr. A to assert himself appropriately and take over control of his life—for example, by learning more about his illness and taking responsibility for his treatment.

WILHELM REICH

Wilhelm Reich (1897–1957) was one of Freud's most controversial disciples; his later years were marred by mental illness (Fig. 6.3–8). Reich fixed on and elaborated Freud's early, but later discarded, view that neurosis results from the damming up of sexual energy. In so doing, Reich laid the groundwork for a psychoanalytic theory of personality. Before Reich, the focus was on symptoms and psychopathology. There was occasional mention of "character" in psychoanalytic work, but there was no focus on personality as an entity unto itself. This shift is of great importance because, as neurobiology has come to explain more and more Axis I mental disorders, it has become clear that one of psychodynamic theory's enduring strengths involves understanding and treating personality traits and disorders. Together with Anna Freud and Hartmann, Reich is regarded as the originator of ***ego psychology***.

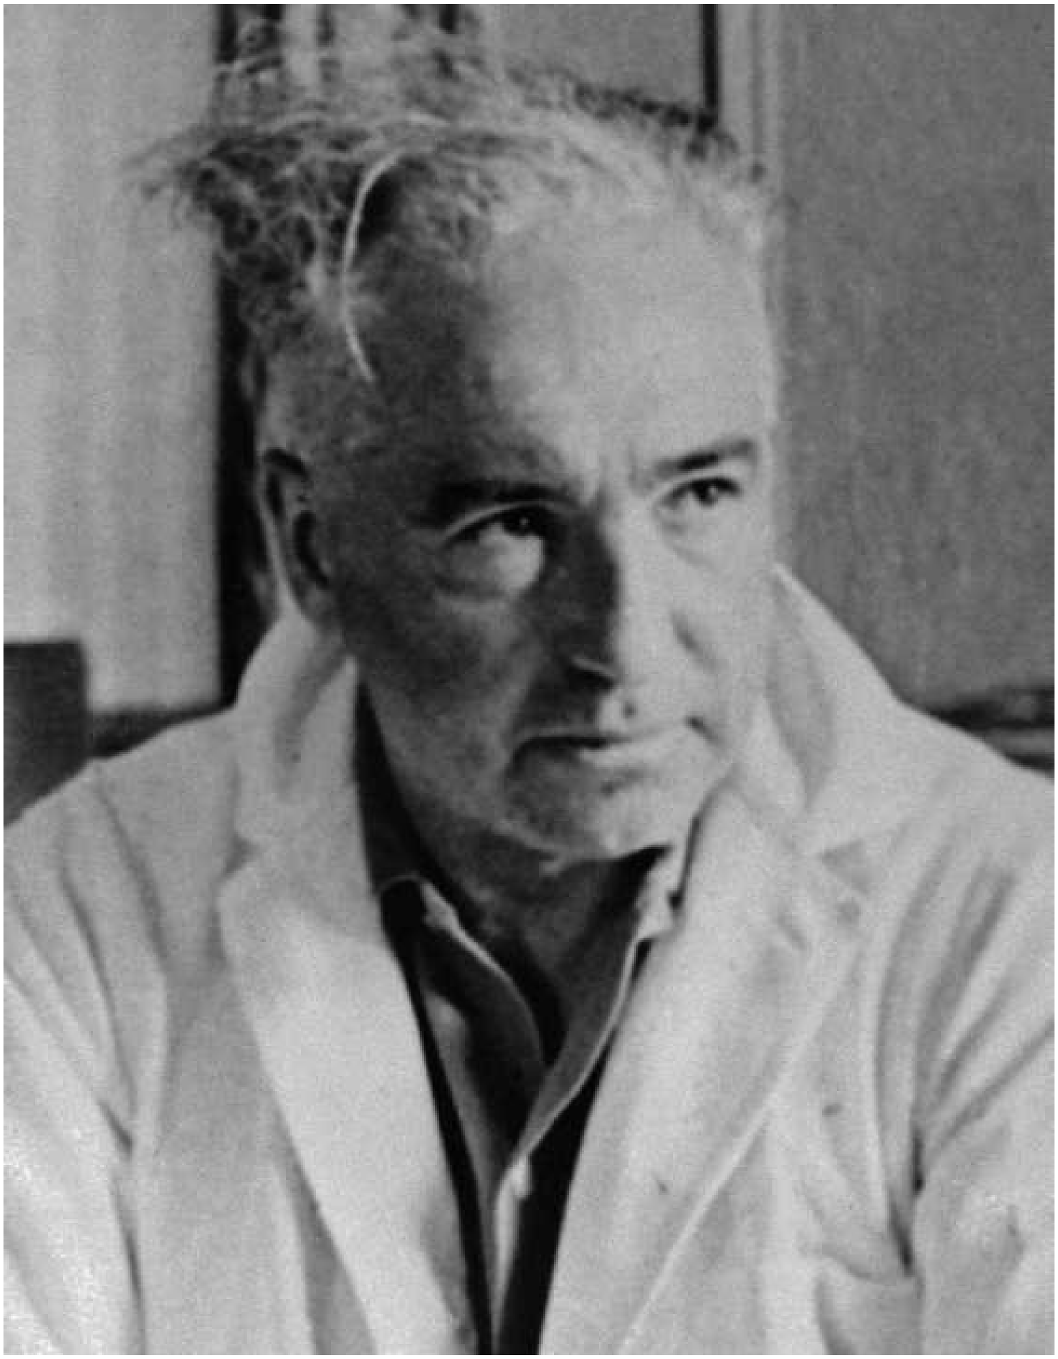

FIGURE 6.3–8. Wilhelm Reich. (Bettmann/Contributor via Getty Images.)

Personality Theory

Reich did not disagree with Freud's notions concerning personality development, including character types based on fixation at specific levels of psychosexual maturation. Reich elaborated on the interpersonal and physical behavior of these personality types. Specific behavioral traits constitute ***character armor*** that defends against internal and external dangers. Character armor is comprised of involuntary, repetitive, ego-syntonic behaviors that prevent the emergence of repressed impulses. For instance, the trait of ingratiation frequently defends against hostile impulses, just as the traits of hostility or self-assertion may defend against wishes to be dependent and passive. These traits manifest physically in the voluntary musculature as characteristic postures (clenched jaw or fist, rigid or bowed back) or in excessive fluidity of movement. Although Reich's ideas of the behavioral and postural components being central features of character armor are no longer accepted, his ideas successfully transformed the focus of psychodynamic thought from individual wishes defended against by individual defenses, expressed in specific transferential forms, into an emphasis on patterns, organization, and intertwining of all of these elements. He also added substantially to the attention paid to nonverbal cues and their implications.

Hysterical Character. The hysterical character has the least body armoring, hence the most lability of function. Body movements tend to be soft, rolling, and sexually suggestive. These individuals are superficial, excitable, flighty, fearful, highly suggestible, and easily disappointed. Their armor helps to defend against easy sexual arousability by flushing out potential sexual stimuli in the environment and then reacting to them with anger.

Compulsive Character. These individuals are tense and restrained, walk stiffly, and sit rigidly. They are overconcerned about orderliness, tend to ruminate, and are indecisive and distrusting. They experience a blockage between their thoughts and feelings. Because they have little access to their feelings, they have little ability to prioritize their actions, make decisions, or sense others' reactions to them. The compulsive character avoids the expression of repressed impulses by rigid overcontrol. Because of this, these individuals are very threatened by trivial changes in routine.

Phallic-Narcissistic Character. Phallic-narcissistic people appear cold, reserved, and prickly. They are outspoken, provocative, and seek positions of power. Frustrated at the genital-exhibitionist stage of development, the men are identified with the penis, and the women with the fantasy of having a penis. The men have strong erective potency but little capacity for intimacy; the women actively dominate men.

Masochistic Character. Masochistic individuals suffer, complain, damage, and deprecate themselves in ways that provoke and torture others. Reich differed from the analytical interpretation that these people enjoy suffering. He believed the opposite—that pleasure is painful for the masochist because of an enormous need, excessive guilt, and the resultant low tolerance for love or pleasure. Suffering allows the masochist to then indulge in a certain amount of self-gratification. Sexual intercourse can be enjoyed, for example, if the partner is inconsiderate or overly domineering.

Treatment

Reich's major contribution was in the realm of treatment. He was the first to recognize the need to deal with character resistances before attempting to recover repressed material, and that interpersonal resistances need to be dealt with before free association is possible. He did this by analyzing patients' character armor—their characteristic behaviors (including tone of voice, posture, and physical movements)—in the analytical setting before proceeding to an analysis of the unconscious. Reich worked face to face with patients and sought to relax their character armor by physical manipulation. This type of therapy, called *vegetotherapy* by Reich, was later practiced by Reich's followers as ***bioenergetics***.

Reichian View of Mr. A

A Reichian analyst might see Mr. A's seeming rebellion against conformity as armor against his fear of being away from his mother's protection and, more importantly, a fear of domination and dependence. The Reichian might point out that the more Mr. A rebels, the more tightly he binds himself to his mother. The therapist might also suggest that the behaviors that seem so much under Mr. A's control are, in fact, masochistic behaviors. His prolongation of his manic states and use of drugs, as well as difficulties with task completion and subsequent praise, help him sustain feelings of need and guilt and avoid those of true pleasure. The "pride" he takes in embracing mental illness may be viewed as deprecation as a way of provoking others and maintaining overall suffering. In addition, the family structure does not allow for the direct provocation of Mr. A's mother. As such, masochistic behaviors may be the only way Mr. A can engage in provocation. Of note, in Reichian analysis, the therapist would specifically attend to nonverbal cues that would reflect this character armor and potentially even work directly with the patient to physically relax their body posture.

KAREN HORNEY

Physician–psychoanalyst Karen Horney (1885–1952), who emphasized the pre-eminence of social and cultural influences on psychosexual development, focused her attention on the differing psychology of men and women and explored the vicissitudes of marital relationships (Fig. 6.3–9). She was one of three women whom Freud trained specifically to have female analysts who would contribute their unique perspective to the psychoanalytic theory about women; the other two were Anna Freud and Helene Deutsch. Horney's view that repression and sublimation of biologic drives are not the primary determinants of personality development led to her removal as an instructor in the New York Psychoanalytic Institute and her founding, in 1941, of the American Psychoanalytic Institute.

Personality Theory

Horney believed that personality development results from the interaction of biologic and psychosocial forces that are unique for each individual. At the core of each personality is an enduring real self, which combines choice, will, responsibility, and identity with spontaneity and aliveness. A natural unfolding process of self-realization leads to the development of human potential in three basic directions: toward others, to express love and trust, against others, to express healthy opposition, and away from others toward self-sufficiency. Horney proposed three main character types, which are based on the predominant mode of relating to others. The *compliant, self-effacing type* results from the defensive operation of clinging to others. These individuals try to curry favor with others, subordinate themselves, and are reluctant to disagree. The *aggressive, expansive type* results from moving against others and relies heavily on power and mastery as a means to achieve security. The *detached, resigned type* results from moving away from others in an attempt to avoid both dependency and conflict. These are very private individuals who, although refusing to compete openly, see themselves as rising above others.

FIGURE 6.3–9. Karen Horney. (Bettmann/Contributor via Getty Images.)

Horney believed that all human beings have basic anxiety, which she saw as the normal response to the infant's helplessness and separateness. Although conditions during childhood may block psychological development, healthy growth is always possible if the internal blockages can be removed. How families respond to a child's anxiety, guided by cultural norms, determines whether individuals spend their lives struggling with basic anxiety or pursuing self-realization. To Horney, attributes of passivity and suffering were not biologically determined or specific to women, as taught by the analysts of her day. She believed that male and female personalities are, in fact, ***culturally determined***.

Horney asserted that differences between men and women were not simply based on anatomical differences and biology but also on differences in role expectations. She suggested that from birth, girls are treated as second-class citizens who are seen as inferior to boys. Expected gender roles encourage women to be dependent on men for “love, wealth, care, and protection.” Societal views of women placed their worth and value in the role of wife and mother alone. Because culture shaped expectations, a woman’s value was assumed to be derived from connection to and relationships with men and children. Women were not seen as valuable in their own right but only as a function of their place in the family and home. Horney wrote, “Women’s efforts to achieve independence and enlargement of her field of activities are continually met with a skepticism which insists such efforts be made only in the face of economic necessity, and that they run counter to their inherent character and natural tendencies. Accordingly, all efforts are said to be without any vital significance for women whose every thought should center upon the male and motherhood.” Horney criticized the androcentric nature of psychoanalysis and the focus on male development and sexuality, suggesting that women’s ability to become pregnant and bear children were underappreciated and neglected. She emphasized the importance of cultural factors in women’s position as inferior and suggested women were not envious of the penis (as was suggested by psychoanalytic theories of the day), but rather the superior position held by men in society. Furthermore, based on her clinical data, she asserted that womb envy in boys was at least as likely as penis envy in girls. Horney’s beliefs about the cultural influence of personality development led to the emergence of feminine psychology and an increased focus on the development of girls and women.

Theory of Neurosis

Horney defined neurosis in both intrapsychic and interpersonal terms. She noted that her patients complained not of the symptomatic neuroses, such as phobias and compulsions, but of unhappiness, blockage, lack of fulfillment in their work, and inability to establish or maintain relationships. She saw these individuals as having a complex system of self-perpetuating defensive patterns against basic anxiety—***character neuroses***.

Safety-seeking children move psychologically in three directions to relieve their anxiety, make life safe and predictable, and achieve satisfaction. They seek affection and approval, become hostile, or withdraw. Children eventually use the coping strategy that best meets their needs, but if only one basic strategy is used, children become limited in their coping repertoire and in their experience of themselves and their world. Their sense of safety is tenuous because there is now danger from within, from suppressed or repressed feelings and impulses. Given continued unfavorable environmental conditions, conflicting feelings are driven into the unconscious, and such children are left with a sense of discomfort, anxiety, apprehension, and an insecure sense of self. At this juncture, their point of reference is externalized; patterns of behavior become more rigid and increase blockages to growth and development. Horney designates these complex, relatively fixed attitudes toward self and others as ***neurotic trends***.

Idealized Image. Individuals who grow up to be neurotic create an ideal image that, if achieved, promises to end their painful feelings and provide self-fulfillment. The idealized image covers over all the contradictions, conceals the defensive nature of their behavior, and restores a sense of wholeness. Energy formerly available for self-realization is now used in efforts to become like the idealized image. For example, an individual who has adopted the strategy of moving toward others and is consequently dependent on others for affection and approval experiences the fear of reasonable self-assertion, striving instead for saintly humility and considerateness of others.

Neurotic people are easily bruised by confrontation with reality and work excessively to prove they are, in fact, their ideal selves. This results in a type of perfectionism that insists on flawless excellence in which “I should” replaces “I want” or “I need.” It also results in the neurotic ambition to be first and fosters a strong drive for revenge against those perceived as having interfered with their efforts to match the ideal self. This aspect of Horney’s theories anticipates some of Heinz Kohut’s ideas on the origins of narcissism.

Claims, “Shoulds,” and Self-Hatred. Despite their frequent self-disparagement, neurotic individuals expect to be treated as though they were their ideal selves. These claims to special treatment, when frustrated, produce anger, righteous indignation, and resentment. The “shoulds,” or self-imposed demands that they live up to their idealized selves, are irrational and unrelated to the realities of daily life. They are projected, experienced as demands made by others, and are also demanded of others. This results in neurotic people being critical of others and very sensitive to criticism themselves. Self-hatred results when the threat arises that neurotic individuals may be unable to achieve their idealized selves. If support is not needed for the idealized self, claims, shoulds, and self-hatred are not such important parts of the psychic apparatus.

Neurotic Pride and the Pride System. Glorifying aspects of the idealized self, *neurotic pride*, substitutes for healthy self-confidence. Thus, when their pride is injured by others, neurotic individuals become enraged and seek to avenge their injury and conceal their self-deception by achieving a vindictive victory over the offending person. Together with supporting claims and shoulds, neurotic pride and self-hatred form a defensive network or pride system that protects the idealized self. Despite the armoring of their defensive network, such individuals are not at peace because they are in inner conflict with the forces that protect them. The conflict between the forces driving toward healthy self-realization and the pride system is the *central inner conflict*.

Alienation. ***Alienation*** from self is one of the most serious consequences of neurotic development. It results from the combination of repeated denial of external reality and the repression of genuine thoughts, feelings, and impulses. As the process of alienation continues, neurotic individuals lose touch with the core of their being and can no longer determine or act on what is right for them. Their feelings may range from uncertainty and confusion to inner deadness and emptiness.

Therapeutic Process

Horney did not regard adult neurotic people as recapitulating childhood experiences and thus did not focus on the recovery of childhood memories; she dealt instead with the self-perpetuating neurotic process. She stressed the importance of dreams in analysis. As unconscious attempts to solve conflicts, dreams can show constructive forces at work that are not yet discernible in patients' conscious thoughts and behavior. Later, she stressed the exploration of the patient–analyst relationship. She was one of the earliest analysts to recognize and make constructive use of her own feelings toward patients. To Horney, psychoanalysis was a cooperative venture that enabled patients to free themselves from their neurotic structures and mobilize themselves toward self-realization. The analyst's responsibility was to assist in liberating patients from *blockages*, the forces that impede healthy growth.

Early in therapy, termed the *disillusioning process*, the two types of blockages are identified and examined. The first group of safety-oriented blockages, *protective blockages*, helps to avoid the anxiety caused by self-awareness. They include silence, lateness, depreciating the analyst, the use of drugs, and even the use of self-accusation as a means to avoid further exploration. *Positive-value blockages* reinforce patients' satisfaction with themselves and support their idealized selves. In the disillusioning process, the analyst identifies both types of blockages, exposing the protective blockages before exposing the blockages that defend the idealized image. Analyzing the positive-value blockages first arouses too much fear. As the central conflict is resolved successfully, patients move into the final phase of treatment: the discovery and use of their real inner self.

Horney's View of Mr. A

From the standpoint of Horney, Mr. A's process of self-realization has been blocked in all three directions. He has not developed the ability to love and to trust; he expresses opposition in an unhealthy way, and he has made self-defeating moves toward independence. He is seen as having developed a detached style of relating to others, having substituted hypomania and the use of drugs for real relatedness. He justifies his illness by taking pride in it. His goal of becoming a writer is part of the development of an ideal self that is a detached observer. He supports his ideal self by having fantasies of involvement with other writers, by convincing his professor that he was able to write a play as his term paper, and by procrastination. He has become more and more isolated from his real self by denying the reality of the fact that his mental illness and cannabis abuse pose a danger to him and that he was failing in school.

A therapist in the Horney tradition begins by pointing out that Mr. A's drug use and his sustaining of manic episodes are blocking his ability to learn about himself and works with Mr. A toward abstinence from substances of abuse and appropriate use of mood-stabilizing agents. The therapist later begins to point out that Mr. A's pride in his manic episodes serves the purpose of sustaining a false self of boundless energy and creativity. Mr. A is encouraged to decide who he really wants to be—a writer in fantasy or a person able to obtain real satisfaction from real accomplishments and real relationships. His dreams are examined and their themes explored. His omnipotent, messianic dreams are interpreted as evidence of his ideal self and viewed in the light of reality. His dreams of being exposed are interpreted as the fear engendered by his ideal self as a means of defending itself against exposure: "If you expose me, you will be embarrassed and humiliated." Mr. A is supported through his fear of humiliation and the pain of realizing that he has been deceiving himself. His self-loathing is interpreted as the activity of the pride system in defending his ideal self. As he begins to relinquish his ideal self, he will begin to discover and mobilize his real inner self in directions that might not have been predictable at the beginning of treatment.

ERICH FROMM

Psychoanalyst Erich Fromm (1900–1980) was often thought of as the archetypical neo-Freudian, the leader among those who emphasized that culture and social setting influence an individual's dynamics as much as instincts do (Fig. 6.3–10). Neither physician nor biologist, Fromm, a native German, received his doctorate in philosophy, sociology, and psychology from the University of Heidelberg in 1922. There he was exposed to a Marxist emphasis on how history shapes societies and how societies, in turn, shape individuals according to economic needs. He was trained as a psychoanalyst at the Berlin Psychoanalytic Institute and then founded, with his wife, Frieda Fromm-Reichmann, the Frankfurt Psychoanalytic Institute. In 1933, he immigrated to the United States and in 1949 moved to Mexico City to found another psychoanalytic institute. In 1974, he moved to Switzerland, where he died in 1980. As much a social critic as a personality theorist, he was later claimed by the existential and humanistic psychoanalysts. Fromm's intellectual agenda was the integration of

Freud’s theory of a dynamic unconscious with Karl Marx’s theory of history and social criticism.

FIGURE 6.3–10. Erich Fromm. (Hulton Archive/Stringer via Getty Image.)

Personality Theory

For Fromm, two central facts dominate human behavior: The inevitability of separateness and the ***historical and social moment*** into which each person is born. He argued that every person yearns to recapture the state of blissful union that existed prenatally. From the moment the baby begins to recognize itself as a separate human being, a titanic struggle begins, pitting the desperate anxiety of loneliness against the urge to fully express and actualize oneself and, ultimately, to transcend the self. Most individuals find the loneliness too painful to bear and suppress their striving for individuation in the service of maintaining the illusion of connectedness. They are socialized by their parents into the roles defined by their society of birth. Fromm actually used the term *symbiosis* years before Margaret Mahler employed it to describe the universal human yearning for fusion, safety, and security while facing aloneness and choosing individuation to lead to freedom and a productive life. However, true freedom is too terrifying for many people, who instead construct a series of illusions that engender the feeling of safety. They create a pseudoself, think pseudothoughts, and experience pseudofeelings in support of these illusions, thereby cutting themselves off from the fullness of their own inner lives. Fromm saw Freud's theory as a special case of his own more general ideas. The illusions that Victorian society offered involved sublimation of sexuality and aggression in the service of social respectability. Social respectability, in turn, provided the illusion of acceptance and security. In other places and at other times, different solutions might be offered. Early in World War II, shortly after his escape from Nazi Germany, Fromm wrote about the willingness of people to give up their freedom to serve an authoritarian society. In the 1950s, he wrote of the pursuit of material acquisitions in the service of postwar productivity, leading to self-satisfied conformity.

To achieve true freedom, Fromm said four basic human needs must be met: *relatedness*, *transcendence*, *identity*, and a *frame of orientation*. *Relatedness* is the need to feel connected to other humans. *Transcendence* refers to rising above basic instincts. *Identity* is the need to feel accepted yet unique. Emphasis on the need for a *frame of orientation* led Fromm late in his career to an exploration of the constructive and destructive roles that religion may play in individual lives.

Theory of Psychopathology

As a social philosopher and critic, Fromm did not really develop a systematic theory of psychopathology. He identified three major mechanisms of retreat from individuation. Some individuals, he said, may seek an authoritarian solution, trying to live through someone or something external to themselves to achieve a sense of adequacy. Others may become destructive, attacking anything that confronts them with their separateness and aloneness. Most individuals develop a conformist attitude, warding off the anxiety of experiencing their own intentionality by accepting socially offered thoughts, roles, and attitudes.

These mechanisms result in four unproductive orientations or ***characters*** typical of modern capitalist society: *receptive*, *exploitative*, *hoarding*, and *marketing*. The *receptive character* often appears to be cooperative and open; however, the primary agenda is to establish a passive relationship with a leader who solves problems magically. *Exploitative characters* are likewise interested in filling themselves up from the outside; however, they aggressively manipulate and usurp whatever reduces their terror, for example, power. *Hoarders* collect, store, and close in on themselves, often being cold and aloof in their efforts to feel secure. *Marketers* treat themselves as a plastic commodity to be manipulated as needed to achieve externally validated success.

Treatment

Fromm wrote nothing at all on the practice of psychotherapy; therefore, what is known is derived from anecdotal reports by those who studied with him or were treated by him. They report his emphasis on a tender and empathic inquiry into the self-deceptions and illusions created by patients in their efforts to ward off the anxiety of separateness and to maintain some sense of connectedness to significant others. He placed great emphasis on the tendency of unloved children to identify intensely with parental values to capture the magical safety they seem to offer. At a time when most psychoanalysts were preoccupied with detailed examinations of the instincts and defenses, Fromm contributed a sense of the range and richness of inner experience that underlies superficial adaptation. He contributed the sense that a new authenticity could be found by those willing to confront the truth about themselves with all its terror of aloneness.

Fromm’s View of Mr. A

In some respects, Fromm’s ideas are uniquely applicable to Mr. A, who is clearly maintaining the illusion of his separateness by conforming to the socially sanctioned role of the rebellious artist. The bipolar I disorder becomes an unexpected weapon in his battle with his terror of aloneness. The dread in the hotel lobby dream is probably the closest this fear comes to consciousness. Fromm would gently probe this dream and Mr. A's self-image. He would point out the chains created by Mr. A's seemingly rebellious independence. The self-destructive quality of the patient's lifestyle would also be confronted and investigated. Ultimately, Mr. A has to experience his own loneliness and face his terror of it to find true freedom, true intimacy, and an authentic self-definition.

HARRY STACK SULLIVAN

Harry Stack Sullivan (1892–1949) is generally acknowledged as the most original and distinctive American-born theorist in dynamic psychiatry (Fig. 6.3–11), and most American psychiatrists make significant use of concepts and approaches he developed. For many years, the primary theoretical dispute within dynamic psychiatry circles was between the classic Freudians and the Sullivanians (or interpersonal psychoanalysts). When psychiatrists use the term *parataxic distortion*, apply the concept of self-esteem, consider the importance of preadolescent peer groups in development, or view a patient's behavior as an interpersonal manipulation, they are applying concepts Sullivan first proposed.

Sullivan graduated from medical school in Chicago in 1917. From 1921 to 1930, he worked with patients with schizophrenia at St. Elizabeth's and then Sheppard and Enoch Pratt Hospitals, where he developed a reputation as a remarkable clinician with an uncanny ability to communicate with floridly psychotic patients. He initiated the first of what are now called ***therapeutic communities***. Later, he entered private practice in New York and eventually returned to the Washington, DC area, where he was involved in clinical, consulting, and teaching activities. In the 1920s and 1930s, he wrote a number of papers on schizophrenia, later collected in *Schizophrenia as a Human Process*. His other books were compiled from his lectures by his students; most were published posthumously, explaining some of the density and seeming disorganization of his written work.

FIGURE 6.3–11. Harry Stack Sullivan. (Courtesy of the New York Academy of Medicine.)

Personality Theory

Sullivan rejected the Kraepelinian dogma of his day that dominated psychiatric thinking about schizophrenia. In searching for alternative understandings of psychosis, he initially turned to Freud but rejected his theories as increasingly rigid and dogmatic. Thus, he developed his own working theory of personality, psychopathology, and therapy.

Sullivan believed language could be misleading and was therefore wary of self-reifying conceptualizations that led to rigid theories. He emphasized the psychiatrist as participant/observer in the clinical situation seeking to keep observations as objective as possible while recognizing the difficulty this presented in dealing with private emotional experience. What can be observed is the social interaction of patients; thus, he defined ***personality*** as the "relatively enduring pattern of interpersonal relations which characterize a human life." From the outset, his focus was very different from the intrapsychic emphasis of psychoanalysis. By approaching psychopathology in this way, he necessarily created a field theory, characterized by temporal and interactive processes, rather than a structural theory.

Sullivan's theory is fundamentally one of needs and anxiety. *Needs* are divided into needs for satisfaction and needs for security. *Anxiety* occurs when fundamental needs are in danger of not being met and is the primary motivator of human behavior. Needs for satisfaction include physical needs (e.g., air, water, food, warmth), and emotional needs include need, especially for human contact and for expressing one's talents and capacities. Because infants are utterly unable to meet their own needs, provision of basic physical needs by caretakers and interpersonal relationships are crucial. Decades before Mahler wrote of a symbiotic stage in infant development, Sullivan spoke of the "empathic linkage" between caretaker and infant and described the complicated interaction of infants communicating tension and anxiety, arousing anxiety in the caretaker, leading to tender responses to the infant's needs. Failure to meet these needs results in loneliness and anxiety.

Sullivan defined *security* as the absence of anxiety. Thus, *needs for security* are defined as the need to avoid, prevent, or reduce anxiety. Needs for satisfaction and security, particularly the lack of such needs being met, can have long-lasting effects on an individual's health and quality of life. Research suggests that social determinants of health, including safety in the home, school, and work environments, engagement in recreational activities, and access to adequate education, health care, and social support (to name only a few) impact the development and exacerbation of mental and physical health disorders. Specifically, deprivation in these and other areas may lead to greater health disparities, limitations to accessing treatment, and increased morbidity and mortality rates. If needs for satisfaction and security are generally met, major negative health effects may not emerge, but anxiety remains inevitable and, as Sullivan theorized, becomes the primary driver for personality development. The *self-system* is defined by Sullivan as the dynamism that is responsible for avoiding or reducing anxiety. Sullivan equated the self, identity, or ego with the individual's developed patterns for avoiding the discomforts that arise from the inability of others to meet one's fundamental needs. It exists, like all else, purely within an interpersonal framework.

The self-system develops a set of mechanisms, called *security operations*, which effect this goal. Security operations function within Sullivan's theory much as defense mechanisms do within psychoanalytic theory. The specific security operations, however, were defined interpersonally, and Sullivan tried to link them closely to actual observation or experience. Some bore the same labels and definitions as Anna Freud's, but Sullivan is best known for three contributions that bore his distinct stamp: apathy, somnolent detachment, and selective inattention. These were drawn from observing the way infants and young children react to painful interactions, such as scolding, with their parents.

The self-system accrues from ever-evolving interpersonal experiences—that is, fulfillment of needs for satisfaction as a result of the empathic linkage with the mother. The most difficult experiences are not necessarily those involving the inability to meet the child's needs but the child's sensing of the caretaker's anxiety in the process of responding to those needs. This arouses anxiety in the child, promotes the need to establish a sense of security, and leads to the evolution of the self-system and the development of security operations. The self-system is divided into three parts. The "good me" is a set of images, experiences, and behaviors associated with an unanxious, tender, empathic, and approving or accepting response from the environment. The "bad me" comes to be associated with ideas, actions, and perceptions that provoke anxiety and disapproval from caretakers. Some situations, however, provoke such intense anxiety that they are entirely disavowed and disowned; they become part of the "not me." Eventually, the empathic linkage becomes unnecessary, and the self-system operates autonomously within the individual, developing ever more subtle and complex ways to manage the person's anxiety.

Developmental Theories. Sullivan had two theories of development, one cognitive, the other social. He postulated three developmental ***cognitive modes*** of experience whose degree of persistence into adulthood is important in understanding psychopathology. The *prototaxic* mode, characteristic of infancy and early childhood, involves a series of disconnected, brief states experienced as totalities with no temporal relationship. In later life, mystical experiences represent persistent prototaxic experiences. *The parataxic* experience begins early in childhood as the self-system begins its more independent functioning. It, too, involves a series of momentary experiences; however, they are now recorded in sequence and with an apparent connection to one another. They may be given symbolic meanings, but rules of logic are absent, and coincidence plays a major role in how the world is perceived. The self-system uses this mode to seek effective anxiety-reducing behaviors and to repeat them, seeking sameness and predictability. Sullivan used this mode to explain transference, slips of the tongue, and paranoid ideation. The *syntactic* mode of experiencing is based on the development of language and consensual validation. The world and the self are perceived within rules of logic, temporal sequencing, external validity, and internal consistency. Thinking about oneself as well as others becomes testable and modifiable based on rigorous analysis of experiences in a variety of different situations. *Maturity* may be defined as an extensive predominance of the syntactic mode of experiencing.

Social development is somewhat based on these evolving cognitive modes. However, disturbed interpersonal relationships may cause persistence of the more primitive (prototaxic or parataxic) ways of experiencing the world. Infancy spans birth to the onset of language and is characterized by the primary need for bodily contact and tenderness. The prototaxic mode predominates, and the primary zones of interaction are oral and, to some extent, anal. Insofar as needs are fulfilled with a minimum of anxiety, the infant experiences euphoria and a sense of well-being. To the extent that some anxiety is commonly present in the caretakers, apathy and somnolent detachment are regularly used as security operations, persisting into adult life as a basic detached and passive stance. If anxiety and inconsistency are severe, intense experiences of dread persist, presenting in later life as the eerie, uncanny, bizarrely disruptive internal states seen in individuals with schizophrenia.

Childhood begins with the onset of usable language, continues until the beginning of school, and is characterized by the child’s focus on the parents as the other from whom praise and acceptance are sought. The primary mode of experience shifts to the parataxic, and the most common zone of interaction is anal. The child needs an approving adult audience. This leads to a variety of learning tasks of language, behavior, self-control, and so on. It can also be observed in a variety of trial-and-error efforts by the child to find what pleases the adult. Gratification leads to an expansive self-system with many facets of life associated with the “good me” and positive self-esteem. Moderate anxiety leads to chronic anxiety, uncertainty, and insecurity. Extreme anxiety results in giving up known successful behavior in favor of self-defeating patterns that fulfill others’ expectations.

The juvenile era covers ages 5 to 8 years. The shift to syntactic cognitive modes begins, and the interpersonal focus spreads to the peer group and outside authority figures. Peers and teachers have the opportunity to approve and accept behavior previously frowned upon within the family (e.g., talking dirty with one’s friends). Interpersonal cooperation, competition, play, and compromise become the gratifying experiences. Juveniles learn to negotiate between their own needs and legitimate social concerns without sacrificing their self-esteem in the process. The risks of excessive anxiety are either too great a need to control and dominate social situations, or they become an internalization of restrictive, prejudicial social attitudes.

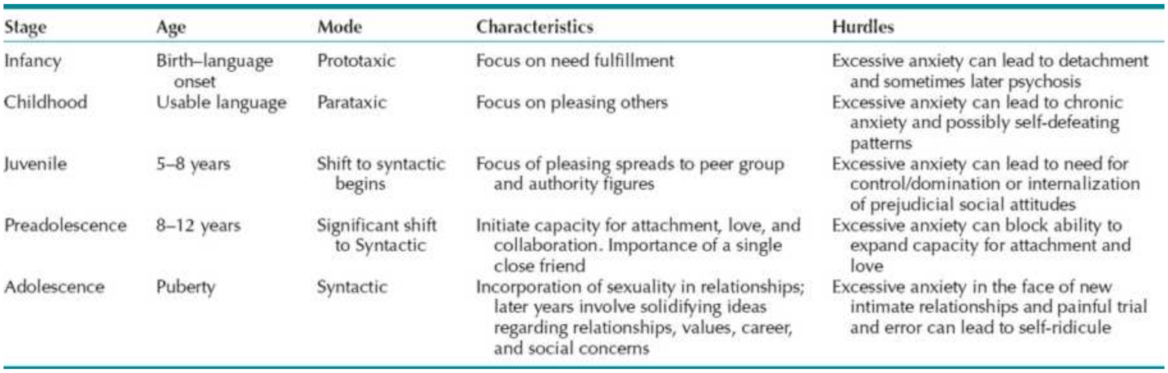
Preadolescence, ages 8 to 12 years, marks the child’s movement from peer group cooperation and competition based on roles toward genuine intimacy with what Sullivan called a chum or a best friend. Sullivan saw this phase as a particularly important stage in which the give and take of the friendship could repair and undo distortions that resulted from excessive anxiety at earlier stages. This is the point at which the individual truly moves outside the family and engages in free, creative interaction with another person unfettered by the same dynamics. During this stage, the major shift toward syntactic thinking takes place, although some distortions may persist into adolescence. The preteen years see the initiation of a capacity for attachment, love, and collaboration or their inability to develop these in the face of excessive anxiety. Although sexual exploration may be a part of the friend relationship, Sullivan did not see sexuality as a central element in this developmental phase.

Adolescents, beginning at puberty, are seen to have concerns similar to those of preadolescents, except that sexual desire is added to the interpersonal equation. Thus, the same needs for a relationship persist but shift to the other sex for their outlet, wherein a major opportunity for learning or severe anxiety begins. As the person faces culturally defined stereotyping, many new opportunities for social experimentation may lead to consolidation of self-esteem or self-ridicule. The struggle to integrate lust with intimacy is accomplished by painful trial and error. If this is completed with the self-system relatively intact, the later years of adolescence are an opportunity to expand the syntactic mode to such areas as a consensual view of interpersonal relations, values and ideals, career decisions, and social concerns (Table 6.3–2).

Theory of Psychopathology

Sullivan abhorred diagnostic labeling for being unhelpful, overly restrictive, and dehumanizing. In discussing schizophrenia, he said, “We are all much more simply human than otherwise.” Thus, he sought to understand the fundamental human process within his patients, especially his sickest ones. He saw psychopathology as resulting from excessive anxiety arresting development of the self-system, thereby limiting both opportunities for interpersonal satisfaction and available security operations. He viewed psychiatric patients as struggling to maintain their self-esteem with very limited means. To understand them, the developmental phase at which they operate has to be gauged, and the interpersonal needs they express have to be understood.

Table 6.3–2.
Sullivan’s Social Development Theory



Stage	Age	Mode	Characteristics	Hurdles
Infancy	Birth–language onset	Prototaxic	Focus on need fulfillment	Excessive anxiety can lead to detachment and sometimes later psychosis
Childhood	Usable language	Parataxic	Focus on pleasing others	Excessive anxiety can lead to chronic anxiety and possibly self-defeating patterns
Juvenile	5–8 years	Shift to syntactic begins	Focus of pleasing spreads to peer group and authority figures	Excessive anxiety can lead to need for control/domination or internalization of prejudicial social attitudes
Preadolescence	8–12 years	Significant shift to Syntactic	Initiate capacity for attachment, love, and collaboration. Importance of a single close friend	Excessive anxiety can block ability to expand capacity for attachment and love
Adolescence	Puberty	Syntactic	Incorporation of sexuality in relationships; later years involve solidifying ideas regarding relationships, values, career, and social concerns	Excessive anxiety in the face of new intimate relationships and painful trial and error can lead to self-ridicule

Sullivan believed that several factors could play a role in the particular form that these disturbances might take. The level of anxiety at particular developmental stages can lay the groundwork for a developmental arrest. Basic cognitive capacity might play a role in the choice of security operations relied on or retained. The degree of success achieved interpersonally combined with whatever capacities are used affects later success. Finally, the chance occurrence of stresses encountered during life is deemed a factor. Thus, Sullivan theorized that anyone might develop schizophrenia, even people with relatively successful developmental histories, should their chosen defenses fail dramatically and their life stresses mount in the extreme. However, it was more likely that patients with schizophrenia would be highly vulnerable along all four dimensions, whereas others with greater developmental strengths might become obsessive, hysteroid, schizoid, or paranoid.

Interpersonal Psychotherapy

Sullivan's ***interpersonal psychotherapy*** approach emphasized that the psychiatrist is a participant–observer in all interactions with patients. He thought deeply and extensively about the nuances and opportunities involved in this unique situation. By interacting actively with patients, verbal and nonverbal expressions of recurrent interpersonal patterns become apparent. These observations then inform the therapist's further behavior, thereby creating the opportunity for change. This process occurs over the seconds and months, and years as the psychotherapy unfolds. Sullivan saw this perspective as an antidote to what he perceived as the wrongheaded emphasis on objective neutrality embodied by the "blank screen" model of psychotherapist behavior. He argued that parataxic distortions emerge in all interactions, not only in the classic analytical situation. This differing view of transference and of it being a universal human process was among the core debates for decades between classic analysts and interpersonal analysts.

Sullivan saw therapy as elucidating the patient's interpersonal patterns, exploring their usefulness in the service of the patient's needs, and considering alternative, more favorable possibilities. Thus, he shared the ego psychologists' understanding that even the sickest behavior was the best adaptation available at a given moment to the patient. He emphasized the experiencing of the distortions, the needs, the patterns, and the potential changes within the ongoing interaction with the therapist.

He saw great power in the very entanglement of the therapist with the patient and recognized the ability of a skilled therapist to manage the interpersonal process to reveal patterns and to shape the patient's emotional experience. However, he constantly emphasized and respected the ultimate autonomy of his patients, who could still, in the end, choose not to reshape their approach to the world.

Sullivan viewed psychotherapy as divided into four distinct stages: *inception*, *reconnaissance*, *detailed inquiry*, and *termination*. *Inception* involves the very beginning, often only a part of the first interview, during which the contract and roles are stipulated. *Reconnaissance* might go on for as many as 10 to 15 sessions, during which the therapist identifies the patient's recurring patterns and assesses their adaptive and maladaptive qualities. The *detailed inquiry* is a very lengthy process of exploring the patient's thoughts, feelings, and memories and evaluating and re-evaluating data from earlier stages, seeking to recognize, clarify, and change persistent parataxic distortions. The recurrent patterns are discussed within the context of the person's developmental history, needs, anxieties, failures, and successes. There is often much ongoing interchange between patient and psychiatrist as feelings and perceptions are validated or questioned within the context of mutual emotional interchange within each session. *Termination* is a product of the evolving contract and understanding between the patient and therapist and may reflect either extensive or limited goals. Sullivan emphasized the constant reassessment of goals by the therapist and the power of the ongoing negotiation and renegotiation of the therapeutic contract as a means to reveal and change parataxic distortions. The ultimate goal of psychotherapy is to experience as much as possible within the syntactic mode and to broaden the repertoire of the self-system. To the extent that this is achieved, individuals are in a position to become responsible for their ongoing growth through subsequent interpersonal interactions.

Sullivan's View of Mr. A

Sullivan would see Mr. A as likely arrested in childhood when his fear of displeasing his mother led him to give up healthy self-esteem strivings for independence in favor of a distant yet dependent position. He uses drugs and psychosis as escapes to maintain some degree of self-esteem. His "good me" consists of his debating and his intelligence. His "bad me" is expressed in his rebelliousness, whereas the "not me" seems to encompass issues of closeness, independence, and constructive engagement with others and with life’s tasks. In therapy, the reconnaissance phase is extremely important, identifying the moment-to-moment interactions through which Mr. A’s security operations interfere with his attempts at constructive independence. His bemusement and detachment are identified, as is his escape into prototaxic thought through drugs and noncompliance with medications. His acceptance of his mother’s management of his trust fund is noted as well. A Sullivanian therapist actively interacts, empathically identifying and confronting Mr. A’s ways of avoiding authenticity and constructive interaction. Once identified, their meanings are gently probed, as are the feelings associated with them. The terror of displeasing his mother and its effects on Mr. A’s ongoing interactions with the therapist are addressed. Interactions are examined for their consequences, with the assumption that the outcome has a bearing on the motivation. Finally, Mr. A is encouraged to try out different ways of relating to the therapist as a prelude to restructuring his outside relationships. He is encouraged to think rationally about his circumstances, to seek a good peer group, develop close friendships, and gradually move away from his near-exclusive focus on his immediate family for all of his interpersonal needs.

ERIC BERNE

Eric Berne (1910–1970) was an American original in both style and substance. He worked in the San Francisco area most of his career, breaking with psychoanalysis in the mid-1950s but never becoming antianalytical, as did many of his followers (Fig. 6.3–12). Like many others, he felt the need to develop briefer treatments than were offered at the time.

A group gathered around him that came to be known as the San Francisco Transactional Analysis Seminars. Through weekly discussions of clinical cases and social and political issues, Berne gradually refined his theory. Berne was wry and provocative in his approach to human behavior, contributing much to “pop psychology” in the 1970s and 1980s. Few clinicians now call themselves transactional analysis therapists; nonetheless, Berne’s ideas remain useful in grasping hidden agendas in human interactions.

Personality Theory

For Berne, the primary motivator of all human behavior is the need for “***strokes***”—attention, recognition, and response from others. Early survival depends on adequate physical contact, stimulation, and nurturance. This need remains strong but later becomes more symbolic and interpersonal. Children rapidly learn what works within their families and practice it extensively. This led to one of Berne’s more widely quoted observations: “Negative strokes are better than no strokes at all.” People evolve ways of interacting with their world to obtain regular strokes in whatever way possible and in whatever way they have been taught to define a stroke (e.g., sympathy in response to chronic depression may provide such gratifying attention that the depression cannot be given up). So great is the need for regular stroking that blatantly destructive actions persist in the face of insight, recognition, and enduring psychological or physical pain.

Like Adler and Sullivan, Berne suggested that hidden social needs motivate human behavior to the extent that, with rare exceptions, there is an interpersonal hidden agenda in all human activity. For Berne, the unit of observation was the transaction, the short-term process of individuals interacting with one another. He spent much energy analyzing transactions to try to discover patients’ definitions of strokes and their preferred mechanism for obtaining them. He noted that most people engage in very predictable, stereotyped, repetitive transactions. The content may vary from situation to situation, but the form tends to be quite rigid. He called these transactions ***games***, and his bestseller, *Games People Play*, captured the imagination of the American public in 1964. Some games are harmless, some are socially encouraged, many have destructive elements or at least limit opportunities for more gratifying relationships (intimacy), and some are highly destructive. A common, socially accepted game is cocktail party flirtation, which is ordinarily pleasant and harmless but, depending on the intensity, frequency, and seriousness with which it is played may cause an inability to experience intimacy, disrupted marriages, or even physical harm.

Berne divided the human psyche into three primary parts: *child, parent*, and *adult*, with two of those further subdivided. He called these *ego states*. An *ego state* consists of characteristic body language, voice qualities, verbal productions, and affective experience. The child represents the persistence of childlike experience and expression in all people. It is divided into the *natural child*, the ego state in which the spontaneity, joy, and intuitive perceptiveness of young children persists in all adults; the *adapted child*, the part that is compliant and cooperative; and the *rebellious child*, the repository of that part of each person prone to fight authority, challenge accepted wisdom, and struggle for autonomy. The parent is the residue of internalized parental messages and injunctions. It is divided into two parts: the *critical parent* and the *nurturing parent.* The *critical parent* bears some resemblance to Freud's superego, embodying rules, values, instruction, criticism, and restrictions. The *nurturing parent* is the internalization of a positive, caring experience, the memory of loving interactions.

Mental health is the flexible availability of all ego states with no one predominating. Excess critical parent produces guilt and depression, but insufficient critical parent produces sociopathy. Excess nurturing parent produces narcissistic laziness, whereas insufficient nurturing parent causes an inability to soothe oneself and to maintain self-esteem. Excess adult results in a cold, overly rational person, but insufficient adult leaves individuals unable to balance the various internal forces in their lives. Too much natural child may result in irresponsible behavior, but not enough depletes the ability to experience joy in living. An overabundance of rebellious child results in self-destructive battles with no constructive purpose; however, insufficient rebellious child may result in an overly conformist stance. Excess-adapted child prevents appropriate striving toward autonomy; insufficient adapted child prevents participation in group or hierarchical efforts.

Berne placed great emphasis on the child's ability to intuit parental messages and instructions, especially those communicated nonverbally and unconsciously. In this way, the growing child might encode a conscious verbal instruction in the critical parent (e.g., be strong, be perfect, be smart), whereas internalizing a more powerful, unconscious message in the child (don't grow up, don't leave me, don't surpass me).

Usually, a model for carrying out the instruction is preserved in the adult (be passive, drink alcohol, run around with women, act crazy). Together, these make a ***script***. Berne emphasized the active role of the child in searching for the messages and in accepting them. This was crucial for him because it emphasized the individual's responsibility in deciding to follow the script, although this might have occurred at a very young age. The entire basis for psychological change lies within the person's capacity, having once accepted the script, to later reject it. However, Berne was impressed by the intensity and persistence with which individuals play out the script throughout their lives. Scripts come in all varieties, ranging from the successful to the utterly self-destructive. Thus, for Berne, the business of human living involved carrying out one's script according to the transactions learned as a child.

Theory of Psychopathology

Given this view of human nature, Berne's understanding of psychopathology is based on the adaptiveness of a person's games and script and the capacity for adaptive use of all ego states. Written at a time when American psychiatry rejected phenomenologic diagnosis, Berne's theories are difficult to accept. However, he did describe numerous clinical situations and case histories that are familiar to all psychiatrists, and he analyzed them according to their scripts. He was very impressed with the role of fantasy and fairy tales in children's development and often asked patients what their favorite story was as a child. He then searched for the hidden identifications and messages within the story to help discern the patient's script. Insofar as he developed a nosology, it lay in the scripts encouraged by culturally sanctioned fairy tales. For example, Cinderella is about a young girl waiting to be rescued by a fairy godmother or a charming prince and unwilling to assert herself against unjust authority. Little Red Riding Hood is about a girl who likes to chat with wolves and gets into trouble trying to please everybody. Men, he found, often identified with the wolf or Prince Charming and were unable to regard women as real people.

A separate nosology of games was also developed and cataloged by Berne. Examples from this nosology include cocktail party flirtation (Rapo I), which concludes with the man and woman having experienced the stroke of feeling attractive and attracted, moving on to other conversations, and seeking other people to attract. Rapo II usually ends with a line like, “What kind of girl do you think I am?” and Rapo III ends up with a painful, destructive affair. Another game is “Why Don’t You … Yes, But.” In its mild, socially acceptable form, one person presents a problem, successfully enlisting the advice of many others; however, for every proffered solution, the person has a ready explanation of why it will not work. The stroke (or payoff) is the attention and the feeling of superiority achieved by defeating others. The second-degree version of this game produces a chronic, helpless depression; the third-degree version may lead to the backward of a state hospital.

There was no rigid mapping of his nosology of games and of scripts, and Berne never claimed that either was exhaustive. They were intended as clinical examples to guide the psychotherapist’s thinking in evaluating each patient who presented unique script and transactional issues. Individuals were assessed according to the straightness of their transactions (Were there hidden communication and invitations emanating from different ego states?), the adaptiveness of their scripts, and the predominant ego state and its effects. Thus, Berne might describe a compulsive person as having too much critical parent or a histrionic person as having too much natural child. In the final analysis, however, he saw his catalogs and nosology as poor substitutes for careful, clinical study of individual patients.

Treatment

Having been trained in psychoanalysis, Berne used many psychoanalytic techniques, but he applied them very differently from traditional psychoanalytic methods. Much of his clinical work was done in groups, with the therapist being very active in confronting and interpreting the interpersonal behavior of the patient. He emphasized the initial contract with the patient and the setting of clear, concrete goals. He encouraged therapists to inquire very early on in therapy, “How will we know when our work is finished?” If a clear and specific answer was not forthcoming, he would inform the patient that therapy had not yet begun. The focus would then be on the patient’s difficulty in defining a recognizable endpoint for the work. Berne’s approach was heavily informed by the psychoanalytic concept of resistance, but he applied it in a very different manner. Berne examined any treatment goal defined by patients for evidence that it was a way to continue playing games or pursuing scripts more effectively rather than giving them up entirely.

Like Sullivan, Berne regarded the ongoing interaction between patient and therapist as the key ingredient of psychotherapy. The therapist's job was to interact actively with the patient; recognize the ego states, games, and scripts being enacted; and counter them using confrontation, interpretation, or various other interpersonal maneuvers that were designed to thwart the enactment and to confront the patient with a choice and an opportunity to relate differently. He emphasized simple direct statements using everyday words to stimulate affective experience and interaction. Commonly, interactions began with his inquiry, "What do you want to work on today?" Observers sometimes described his work as individual therapy within a group context because the other patients, who were silent observers, often responded emotionally to the interaction.

Berne placed great emphasis on the role of individual responsibility for one's life and experience, which he believed had been obscured by the emphasis on psychic determinism. He constantly communicated the opportunity for choosing to continue or discontinue the patterns or habits encouraged as a child. He also showed patients how they invite others to behave in various ways, thereby creating their own interpersonal reality. Health lies in recognizing one's option for deciding which invitations to offer to others and which to accept from others, although these invitations may be communicated unconsciously and nonverbally.

Berne's View of Mr. A

Mr. A is clearly playing a very destructive game and living out a particularly unproductive script. The script seems to contain the messages: "Don't ever leave me" and "act crazy." The message "you must be special" may also exist. The games used might be called "I'm out of control," "Helpless," "Artiste," and "I'm better than you are." A transactional analyst places Mr. A in a group and works with him on these games and scripts. Many such therapists have productively combined Berne's theories with Fritz Perls's empty chair technique. Mr. A might be asked to carry on imaginary dialogues with his mother, professor, his illness, marijuana, and admired writers of fiction, with Mr. A assuming both sides of the dialogue. The transactions he uses are elucidated in this way, and he is invited to recreate the transaction more constructively. His internalization of his mother as an excessively critical parent is identified, and the fantasy dialogues are used to enable more internalization of both his mother's and father's nurturing qualities, which contain other script messages such as “grow up” or “be successful.” Similarly, his excess rebellious child is demonstrated, and efforts to bring it under more adult control are made.

FIGURE 6.3–13. Nancy Chodorow. (Courtesy of Nancy J. Chodorow, Ph.D.)

NANCY CHODOROW

Nancy Chodorow, born in New York, in 1944, is a sociologist, psychoanalyst, and educator (Fig. 6.3–13). She earned her PhD in Sociology from Brandeis University and trained in Psychoanalysis at the San Francisco Psychoanalytic Institute. Influenced, in part, by Karen Horney and Melanie Klein, Chodorow developed a theory of psychoanalytic feminism that incorporated traditional aspects of Freudian psychoanalysis, object relations theory, and feminist views, including a focus on the mother–infant relationship and the impact of gender on development. She is known as a leader in the feminist movement and describes herself as a feminist psychoanalyst. Her seminal works, including *The Reproduction of Mothering: Psychoanalysis and the Sociology of Gender*, have influenced contemporary feminist theory and fused traditional psychoanalytic views with modern-day developmental theory. This book was selected as one of the ten most influential books of the past 25 years by Contemporary Sociology.

Chodorow began her academic career teaching Women's Studies at Wellesley College in the mid-1970s. From there, she went on to join faculty in the Sociology Department at the University of California, Santa Cruz, from 1974 to 1986. Since 1986, she has been a professor in the Sociology Department at the University of California, Berkeley, and in 2005 was named Professor Emerita. Chodorow has won numerous awards and has written many books on feminist psychology and sociology.

Theory of Personality and Gender Identity

Nancy Chodorow's theory combined classical psychoanalysis, object relations, sociology, and feminism. Similar to Freudian psychoanalytic theory, her theory of personality development assumed the role of unconscious drives and dynamics and development of gender identity through relation to the parents, particularly the mother. Yet, Chodorow is an object relations theorist, and it is from this point of view that she proposed a theory of personality development and gender identity rooted in feminist ideas. Where traditional psychoanalysis suggested people are motivated primarily by drives, impulses, and the unconscious, object relations theory proposed people are motivated by seeking relationships with other people ("objects" in psychoanalytic terminology). Chodorow focused more on object relations and children's connection to their mothers than on unconscious impulses and conflicts. Her theory also diverged from classical Freudian ideas by focusing more on development during the preoedipal period than the oedipal phase, although she acknowledged the necessity and importance of resolution of the Oedipus complex. Chodorow emphasized attachments to objects were related to unconscious dynamics between mother and child, but she also acknowledged that children internalize normative gender roles and behaviors based on how and in what environments they are raised.

At the heart of Chodorow’s theory of personality are two primary questions: how do individuals develop gender identity? And why do women (and not men) develop a desire to mother? Psychoanalysis and feminist theory suggest individuals’ personalities are made, not born, and biology alone does not adequately explain the development of gender and personality. In her theory of development, Chodorow explored not only the child’s relationship to the mother but also the mother’s relationship to the child. She suggested that the presence, stability, and consistency of an attentive caretaker are more important than the exclusive bond and attachment between biologic mother and child. The development of personalities of boys and girls differs as a result of the mother’s varied approach to raising and ***mothering*** children based on the sex of the child. Mothers see daughters as like themselves and sons as different from them, resulting in a difference in approach to the mothering relationship with male and female children.

Young children—both girls and boys—have a closer bond with their female primary caretaker early in life and therefore begin to internalize the feminine characteristics of the mother. Girls identify with their mothers because they are similar and will later continue internalizing feminine traits. In contrast, boys will separate from the mother to gain autonomy and increased masculinity. Because boys are encouraged to attain masculinity through separation from the mother and her feminine attributes, masculinity is viewed as difficult to attain and therefore idealized and fantasized about for both male and female children. This valuation of masculinity as something to be sought, versus femininity as something to be left behind, contributes to and rests upon the generalized (and societal) evaluation of masculinity and, therefore, maleness or manhood as more valuable than femininity, femaleness, and womanhood. Successful development for female children involves growing in relation to others, where optimal development of male children lies in disconnection and separation from others, particularly the mother.

Through mothering a girl, the mother re-experiences herself as being mothered and feels like her daughter. This connection and closeness make gender identity for girls easy, innate, and more stable, as daughters develop a sense of sameness with their mother and have an immediate and accessible model of the female gender. Girls are less avoidant of revealing their vulnerability and dependence on others compared to males. Girls also develop a sense of connection, closeness, relatedness, and a sense of permeability of boundaries in personality development. Girls' personalities are anchored in relation to others and relationships, which makes them more stable than males.

For boys, gender identity is more difficult, as they begin to separate themselves as being unlike their mother. Boys cannot rely on connectedness and closeness with the mother to establish a sense of gender identity and begin to look for sources of masculinity from which to model, including male caretakers, other male authority figures, and even superheroes. As a result, boys develop personalities that are autonomous, independent, with firmer boundaries than girls, and with less emphasis on relation and connection. Boys must reject attachment and dependency on the mother to find and maintain masculinity, leading to greater challenges and complexities with male gender identification compared to that of females. Because male gender identity is based foundationally on not being something (feminine), it is more fragile and less stable, requiring reconstruction and affirmation along the way in development.

Unfortunately, because masculinity is psychologically constructed as opposing femininity, one way to affirm masculinity is to denounce or condemn femininity, which leads to the derogation and disparagement of girls and women. Boys are taught to be masculine rather than feminine, and a boy's masculinity is focused more consciously than a girl's femininity. Although masculinity may be foundationally less solidified, it is also more valuable and worthy of maintaining compared to femininity.

In sum, early gender differences are rooted in how girls are able to remain identified with their mother, while boys must reject this identification and establish a separate masculine identity. These initial differences are greatly reinforced throughout childhood by domestic and social gender roles. Such gender roles generally encourage girls to assume tasks of domestic activities and caretaking, whereas boys are encouraged to become independent with activities focused outside the home and family. As adults, men's and women's different roles within the family are supported by gender-stereotyped ideals, particularly that women mother and focus on activities within the home and that men are heads of the household and focus on activities outside of the home. Women are seen as being most effective in roles that require connectedness and relation to others, while men may be successful and effective in roles that do not require connection to others. This can also be interpreted as women’s focus and work being related more to emotional experiences than men’s, which perpetuates the expectation that women will be responsible for emotional labor in the home. Personality traits of men and women are oriented toward the differences in the division of domestic and vocational roles associated with each gender. As Chodorow noted, “The sexual division of labor and women’s responsibility for child care are linked to and generate male dominance.” This cycle is perpetuated and supported by gender roles learned early in childhood and by women’s continued mothering of children.

Parenting Roles. Chodorow’s clinical experience and the conventional wisdom at the time suggested that women, but not men, want to mother (provide nurturance and serve as primary caretaker). Chodorow asserted that women choose to mother and are not biologically destined or hormonally driven to do so. She suggested a woman’s anatomical and biologic makeup provide for why she can become pregnant, give birth, and nurse children, but does not account for why she should or would mother children. Research on hormonal differences between men and women does not support physiologic reasons for women’s role as the mother compared to men’s. Although hormonal changes occur that are directly related to pregnancy, parturition, and lactation, these do not explain the continued care provided to children after such hormones dissipate. Chodorow indicated girls and women are socialized to mother and encouraged through family dynamics, sexual division of labor in the home and work environments, and societal expectations to bear and care for children. She used the example of young girls being “wrapped in pink blankets and given baby dolls” and not being “allowed to get dirty” to highlight early socialization toward domestic activity, nurturing behavior, and motherhood.

Chodorow believed that women’s ability to bear and nurse children were not a sufficient explanation for why they then do most of the caring and mothering. She considered other sociologic and economic theories about why women mother but concluded that they do not completely explain why women want to mother. These theories included societal expectations to serve the role that evolution and biology intended, or individual motivation to become economically supported by serving the role of wife and mother and becoming attached to a financially successful man. Instead, Chodorow argued women get the desire to mother by having been mothered by women themselves. She challenged the notion that women are born with maternal instincts or motherliness. She suggested the biologic clock and maternal instincts were shaped by unconscious fantasies and a woman's internal relationship to her own mother and are not necessarily instinctual on their own. Chodorow proposed that becoming a mother should be and is a choice rather than the assumed fate of women and biologic females.

In her 1978 book *The Reproduction of Mothering*, Chodorow argued that mothers are the primary caretakers (not because of biology, but because of the absence of the father, who is presumed to be working and not expected to be involved in parenting). She theorized that if parenting roles were modified and men spent more time in fathering and parenting activities, boys and girls would get equal representation of both male and female parents in the home, and gender identity development would be reshaped, resulting in social change and change in perceptions of gender roles. The relationship between mother and infant forms the basis from which boys and girls develop relational abilities and connections to others. It is from this first relationship that children learn the capacity for potential parenting that may be utilized in adulthood, as, regardless of sex and gender, both women and men are mothered as children. The early relationship to the mother results in both boys and girls developing a capacity for and sense of ability to participate in parent–child relationships and to provide adequate parental care.

Chodorow's theory about mothering and the mother–child relationship emerged at a time of change in culture and the beginning of a change in society's view of women. With feminist beliefs emerging and gaining ground in the 1970s, Chodorow's theory followed from a growing awareness that the view of women's role as primarily mother and homemaker was oppressive. In her updated preface to the second edition of *The Reproduction of Mothering*, written in 1999, Chodorow noted that fathers' increasing involvement in rearing and parenting children over time may have been in response to cultural shifts in the view of men's role within the family, changes in perception of masculinity, a response to feminist views regarding women's role within families, or response of needs associated with families in which both parents work full time. Chodorow noted early on that men's greater involvement in parenting would likely have an impact on gender identity and the cycle of development, gender role expectations, and perpetuation of men's and women's perceived roles.

Psychopathology

Psychopathology can arise as a result of various factors, including the mother–child relationship. As toddlers, children began to experience incrementally more autonomy as a function of increased mobility and locomotion. The mother then becomes responsible for managing how and when children move about. As children develop a greater and more separated sense of self, mothers have to balance managing the child's choices with allowing them to make such choices and movements on their own. This transition period becomes challenging as the mother tries to avoid both overprotection (resulting in extended dependence on the mother) and neglect or deprivation (resulting in premature autonomy without sufficient decision-making abilities). Although Chodorow did not directly connect these early life experiences to later pathology, one could assume a potential impact on adult relational interactions based on such experiences with the mother in childhood.

Regarding the mother–son relationship, the increase in emotional distance between mother and son as the male child becomes more autonomous and seeks masculine attachment figures can go too far. This can have negative effects for the child, including becoming estranged from the ability to experience emotions and participate in intimacy (which often requires some amount of vulnerability). Boys may seek external interests, and men may seek multiple sexual partners to avoid the closeness associated with intimate relationships. In addition, boys and men may have difficulty accessing and expressing their emotions and may even become intolerant or denigrating of people, primarily women, who can express their emotional needs, such as the need for love.

For girls, experiences of a prolonged preoedipal phase can result in abnormal or pathologic psychic development ranging from neuroses to psychosis depending on the resolution of the oedipal phase and their ability to differentiate themselves as separate from the mother. Particularly if the mother has difficulty separating from the child, individuation may not occur, and girls' identity development becomes stifled, resulting in an overdependence on the mother. In adulthood, psychopathology for women can also result from conflict between their own motherhood and careers, other interests, or past life choices.

As mothers, women may seek psychological and emotional fulfillment from relationships with their children, particularly when these needs are not provided for by their partners, which may result in overinvestment in mothering. In such cases, mothers may have difficulty differentiating their lives from that of their children. Overattachment can have negative effects on the relationship between parent and child and the child's ability to separate and differentiate from their mother. Similarly, when children serve as a mother's only close relationship, expectations that emotional needs be met can create conflict and discord between mother and child. In addition, Chodorow presented two case studies of women who postponed or unconsciously sabotaged having children and later developed an extreme sense of loss when child-bearing years had passed, and motherhood was no longer an option.

Treatment

Chodorow is a sociologist and feminist, but her approach to treatment remains psychoanalytic. She emphasized the need for people to harness the power of their emotions and to recreate a life story that aligns the unconscious and conscious experiences. The foundation of treatment is relational, acknowledging the real connection between analyst and patient, as well as the influence of the past on the present. Chodorow encouraged recognition of each patient as unique and emphasized the development of a personal therapeutic relationship that allows for navigation of emotional and fantasied content that arises in treatment. The focus of treatment is on affect and the connection between fantasy and reality. According to Chodorow, psychoanalysis should offer an examination of meaning and the use of feeling to analyze how the unconscious creates stories and influences situations that arise in the present. Case examples presented by Chodorow indicate an emphasis on finding the source and reason for internal conflict related to the self and early relationships or attachment figures.

Chodorow's View of Mr. A

Mr. A is having significant difficulty transitioning from adolescent-like behavior to a more adult lifestyle. He does not take responsibility for his choices, including decisions to avoid treating his bipolar disorder appropriately. Although he fears returning to his hometown and living with his family again, he is not able to make the connection between his actions and the resulting consequences or does not have the ability to make the necessary changes required to avoid such outcomes. Mr. A's (and his siblings) relationship with his overattached and controlling mother likely developed early on between mother and child. His mother, who stayed home to raise the children when they were young, may have been challenged by allowing Mr. A and his siblings to gain autonomy and separation as infants and toddlers. Perhaps Mr. A's mother experienced her own conflicts related to being placed in the role of full-time mothering, especially given his father's absence. Because of a lack of autonomy, Mr. A was unable to individuate and formulate an independent sense of self. In addition, because his father was presumably less involved in childcare than his mother, Mr. A had only one model for the parent–child relationship. As Mr. A and his siblings grew up, their father's involvement in childcare was limited to placating the mother rather than parenting the children or encouraging or introducing change within the dynamics of the family, particularly the mother's relationship with her children. Once the children were grown and the mother returned to working outside the home, Mr. A was expected to begin acting like an adult (complete college, begin a career, and be able to support himself). However, his mother maintained control of his life not only through his finances but also through the management of his mental illness.

Mr. A's refusal to effectively treat his bipolar disorder could be seen as an inability to recognize his needs or an active rebellion against an overattached mother. Mr. A views himself as an outsider and perhaps is proud of his mental illness because it sets him apart (even makes him special) compared to others. His refusal to treat his disorder may be an attempt to separate himself physically and metaphorically from his mother and his family, particularly because no one else in the family has a mental illness. His increased and daily use of marijuana and efforts to maintain a state of hypomania may be attempts to control emotions by only allowing access to enjoyable or pleasurable emotions mimicked by both intoxication and elevated mood states. Chodorow's assertion that boys have greater difficulty experiencing and expressing emotions because of their early distancing from the female primary caretaker may be influencing Mr. A's use of marijuana and hypomania as methods of avoiding emotional states altogether. However, this may be in contrast with his overattachment with his mother. Regarding his dreams, Mr. A's flying dream could be a hope or desire to separate himself from his mother and his family, to create an individualized identity and sense of self. The dream about the hotel could represent dread associated with remaining connected to his family and feeling stifled by this connection.

In looking at the formulations and treatment plans, each of these theorists might propose for Mr. A, significant, even contradictory, interpretations become apparent. Commonalities exist but are expressed in different words and concepts. Each of these great thinkers has contributed to the overall understanding of the psychodynamics of psychopathology and treatment.

6.4 Approaches Derived from Philosophy and Psychology

PAUL T. COSTA, JR., PH.D., AND RALPH L. PIEDMONT, PH.D.

All the sciences trace their beginnings back to philosophy, but psychology and psychiatry have particularly strong links. Among the topics of most concern to ancient philosophers were the properties and limitations of the human mind: The exercise of reason, the influence of passion, and the mystery of madness. Philosophers sought to understand how the mind works and how it might be guided and strengthened. Psychiatrists today have much the same goals.

One of the functions of this section is to raise philosophic consciousness by hinting at some of the fundamental ideas concerning human nature that may challenge the implicit tenets of modern psychiatry. It is, of course, impossible to do justice to the full scope of philosophic thought in the space of this section. Four major schools of personality—psychoanalytic, behaviorist, humanistic, and trait—reflect four different philosophies of human nature and have very different implications for the field of psychiatry. Contemporary trait theories of personality reflect the recognition that all three of the other schools or approaches contain a kernel of truth. Are people driven by their impulses? Some are, some are not. Some are habit-bound, some are heroic; people vary in their emotional, interpersonal, experiential, attitudinal, and motivational tendencies. Trait psychology's emphasis on consistent differences among individuals can be seen as an alternative philosophy of human nature, one better suited to pluralistic and diverse societies.

The remainder of the chapter provides an overview of psychological theories grouped under the traditional rubrics of behavioral, humanistic, and trait approaches. Because of its importance in contemporary personality research, special attention is given to the trait perspective, especially the Five-Factor Model of Personality (FFM) and its accompanying-Factor Theory of the personality system.

PHILOSOPHY

The recognition of individual differences is probably as old as human culture, but differences in personality were long confounded with differences in status, class, or caste. Individuals from a higher status were assumed to be superior human beings, more sensitive, honorable, and wise. They were endowed with these characteristics by education, by bloodline, or—in the view of Indian philosophy—by moral behavior in a previous life.

Plato

The first major account of personality in Western thought was provided by Plato (circa 428–348 BCE). In The Republic, he made extended comparisons between the constitutions of different states and the constitution of the soul. Just as every state must have peasants, artisans, soldiers, and rulers, so too must each individual have appetites (for food, sex, and so on), passions (for honor and advancement), and reason. The relative strength of these three determines character, as well as fitness for a particular place in society. Intelligent and thoughtful people ought to rule, and passionate people should be chosen to defend the state, whereas dull and spiritless individuals, lacking reason and passion, should be given the menial chores of agriculture and industry.

Plato assumed that these psychological characteristics, like physical strength or musical talent, were largely inborn, but he regarded them as a property of the individual, not the individual's social status. Although he assumed that high-status citizens would normally bear children of the greatest potential, he specifically acknowledged that there would be exceptions, and, in his ideal state, children of the lower classes would be promoted, and those of the higher classes would be demoted on the basis of their own merit. Here, personality would be the basis of the social order, not vice versa. His most radical extension of this idea was to argue that women should be given social equality and allowed to become soldiers and rulers if they possessed the necessary mental and physical qualifications.

One of the recurring questions in personality theory has been the relative importance of nature versus nurture. Trait psychologists—particularly those interested in the study of temperament—have frequently pointed to innate differences in personality, whereas behaviorists and psychoanalysts have laid great stress on the formative influences of the environment and early childhood experiences. Ready as he was to acknowledge the importance of inborn potential, Plato was also keenly aware of the influence of education. Much of The Republic is devoted to his views on the effects of physical exercise, mental instruction, and poetry and music on the development of personality. Present-day concerns about the influences of video games and rap music on children follow this tradition.

Like most philosophers, Plato was more concerned with understanding virtue and vice than psychopathology, but, because he considered vice to be the result of weak or corrupted nature rather than free but evil choice, his discussions of flawed character can be viewed as early descriptions of what might now be viewed as personality disorders. Just as there are better and worse forms of government for states, so are there also better and worse configurations of reason, passion, and appetite. Plato described five types corresponding to five forms of government. The ideal of mental health, corresponding to government by wise rulers, is one in which reason holds in check passions and appetites. In the arrogant and ambitious type, there is an excess of passion or pride; in the avaricious type, there is an excess of appetite. However, in both of these types, reason still retains some authority; for example, avaricious individuals can control most of their appetites to indulge their desire for money. In the fourth, self-indulgent type, appetites are undisciplined, and, in the debauched, fifth type (corresponding to a government by despot), reason is completely disregarded, and a clearly psychopathological state is reached: “Thus, when nature or habit or both have combined the traits of drunkenness, lust, and lunacy, then you have the perfect specimen of the despotic man.”

Aristotle

Plato’s vivid but rough typology was succeeded by Aristotle’s (384–322 BCE) detailed analysis of human character in the Nicomachean Ethics. Courage, temperance, generosity, pride, ambition, irascibility, friendliness, boastfulness, and shame were all defined and distinguished. Aristotle attributed pathologic variations on these traits to innate defects or to disease processes: “Among all the excesses of foolishness, cowardice, intemperance, and irritability some are bestial, some diseased. If, for example, someone’s natural character makes him afraid of everything, even the noise of a mouse, he is a coward with a bestial sort of cowardice.” He considered variation within the normal range to be the result of training and habit and thus to be subject to praise or blame.

Aristotle’s basic moral precept is the golden mean: He argued that extreme standing on either end of a trait dimension should be avoided. Thus, stinginess and extravagance are vices, whereas generosity is a virtue; similarly, vanity and humility represent excessive or insufficient self-esteem. This conception continues to influence some modern notions of psychopathology, in which marked deviation from the norm in either direction is considered pathologic. Individuals excessively concerned with social attention may be regarded as having a histrionic personality disorder; those insufficiently concerned with social attachments may have a schizoid disorder.

Aristotle carried conceptual analysis to a level that has seldom been surpassed, distinguishing, for example, between the superficially similar qualities of temperance and self-control: Individuals are temperate if they have healthy and moderate impulses that require little control, whereas individuals have self-control only if they have immoderate appetites that are nevertheless held in check. Such considerations allowed him to form rational taxonomies of traits that anticipate the empirical taxonomies proposed by 20th-century factor analysts.

Shankara and Eastern Philosophy

Indian philosophy is a vast body of work that combines early science and psychology with Hindu theology and its offshoots (including Buddhism). Its foremost thinker (from the perspective of mainstream Hinduism) was Shankara (788–820 CE). In a brief life of 32 years, he restored the authority of the ancient Hindu scriptures, the Veda, after centuries of criticism by heterodox schools, and he articulated a worldview that has influenced Indian thought ever since. Shankara argued that the basis of existence was Brahman (the Absolute, Emerson's Oversoul), which pervades everything but is itself indivisible. The physical universe is not, for Shankara, an illusion but a manifestation of Brahman. What is an illusion is the idea that the individual is part of the material world, when in fact, the Self is nothing other than Brahman. Through study and virtuous actions, it is possible to come to understand this fact, leading to a state of enlightenment in which the individual becomes blissfully detached from life while continuing to participate in it.

Although the philosophical rationales vary immensely, much Eastern thought shares the core ideas and ideals of Shankara's system. In particular, Eastern thought emphasizes renunciation and asceticism, not as a way to mortify the flesh but as a way to liberate the soul. Themes of self-transcendence are also seen in the reverence for all life that is common to Hinduism, Buddhism, and Jainism (and that is increasingly seen in Western concerns with the environment).

Eastern philosophy was much admired by Carl Jung, and it had some influence on psychiatric thinking during the 1950s and 1960s. However, despite recent calls for multiculturalism in psychology, there appears to be relatively little interest in the topic today. Yet Eastern thought provides an entirely different perspective on what the goal of psychiatric treatment ought to be: Not palliation of distress or more effective functioning in social groups, but liberation from the illusions that create distress and dysfunction. This goal and the large body of techniques for achieving it developed over the centuries surely merit more serious attention.

Immanuel Kant and Arthur Schopenhauer

The last great period of the Western philosophical tradition, begun by Plato and Aristotle, was inaugurated at the end of the 18th century by Immanuel Kant (1724–1804), whose critical philosophy forms a transition between purely rational approaches to human nature and the empirical sciences that followed. One of Kant's last works, Anthropology from a Pragmatic Point of View, considered natural and moral variations in character and reintroduced the Roman physician Galen's taxonomy of choleric, phlegmatic, sanguine, and melancholic types to modern psychology.

Sciences are usually distinguished from philosophy by their reliance on empirical data, but it should not be imagined that philosophers made no use of experience. On the contrary, like many of the clinicians who offered psychological theories of personality, philosophers based their ideas heavily on their observations of human nature. A striking instance of this is provided by Arthur Schopenhauer (1788–1860), a follower of Kant, whose dark view of the world as a place of purposeless striving had an extraordinary influence on early personality theorists, including Freud and Jung.

One of the central beliefs of Western thought has been that human happiness or misery is the result of external conditions—what is now called quality of life. However, Schopenhauer's acute observations, reported in The World as Will and Representation, led him to propose "the paradoxical but not absurd hypothesis that in every individual the measure of pain essential to him has been determined once and for all by his nature…. His suffering and well-being would not be determined at all from without, but only by…what is called his temperament."

In support of this view, he noted that wealth and power do not make people happy, "for we come across at least as many cheerful faces among the poor as among the rich." He also argued that the effects of great misfortunes or successes are short-lived and that, for the most part, evaluations of the external causes of the state of mind are illusory attributions: “We often see our pain result only from a definite external [cause] and…believe that, if only this were removed, the greatest contentment would necessarily ensue. But this is a delusion…[The pain] would appear in the form of a hundred little annoyances and worries over things that we now entirely overlook.”

Recent scientific research on psychological well-being has confirmed this account in every detail: Well-being is chiefly a function of enduring personality dispositions; wealth, social class, and other markers of the objective quality of life are virtually unrelated to subjective happiness; and processes of adaptation quickly return individuals to their own characteristic baseline of happiness after favorable or unfavorable life events. Schopenhauer’s observations are also consistent with recent evidence on the heritability and lifelong stability of many mental disorders.

Yet, reason and insight are not enough. On the basis of his own experience and the examples of history, Schopenhauer also concluded that “man inherits his moral nature, his character, his inclinations, his heart from the father, but the degree, quality, and tendency of his intelligence from the mother”—a conclusion not supported by the findings of modern behavior genetics. Psychology broke from philosophy over precisely this need to seek empirical verification of hypotheses, but it carried with its concepts and insights accumulated over two millennia of profound thought about human nature.

Jacques Derrida and Postmodernism

Throughout much of the 20th century, philosophers tried to support empiricism by examining the conceptual foundations of the scientific method and inductive inference. Concepts such as operationalism, theory falsification, and construct validity are products of the philosophy of science that have been widely adopted in scientific practice. The most influential philosophical movement of recent years, however, has often been seen as antiscientific. Deconstructionism and its intellectual descendants have provided a radical critique of conventional scientific thinking that has had a marked impact, for good or ill, on the humanities and social sciences.

Jacques Derrida (1930–2004) was a French philosopher who is usually identified as the founder of deconstructionism. Through analyses of literature, history, and psychoanalysis, he questioned the basic tenets of

Western thought. He drew attention away from the ostensible subject of any writing, pointing to the writing itself as the object of investigation. Following this lead, social constructionists argued that there is no objective reality for science to study; instead, reality is constructed as a product of language and culture.

Derrida has had an enormous impact on the humanities, which is seen in the scholarly journals that abound with references to discourse, text, and narrative. In combination with other influences, such as feminism, social constructionism, and multiculturalism, deconstructionism has led to postmodernism, a stance that is critical of conventional empirical science on several accounts. Postmodernists argue that science is a set of cultural conventions revered in the West but is ultimately no more valid than any other belief system. The evidence that a Darwinian offers in favor of evolution is no more convincing than the evidence that a Fundamentalist offers in favor of creationism. Both are discourses that have their own justification. Postmodernists are also critical of the claim that science is value-neutral. They argue that the enterprise of science is inextricably bound to value judgments, and they have pointed out numerous ways in which science has contributed to the oppression of women, minorities, and members of non-Western cultures.

Many psychoanalysts, humanistic psychologists, and anthropologists have embraced postmodernism. Within psychiatry, one of the pioneers of postmodern thinking is Thomas Szasz, who argued that mental illnesses are not objective medical conditions but questionable value judgments. Kenneth Gergen has urged psychologists to adopt a postmodern perspective to liberate their science from orthodox methods and theories and to make psychology more relevant outside Western culture. Mainstream psychologists, like most psychiatrists, tend to view postmodernism skeptically; indeed, many reject it outright.

However, the criticisms and alternatives offered by postmodernists can be useful to empirical scientists, even if the radical premises are not accepted. Some of the qualitative methods they advocate, such as content analysis, can provide a valuable supplement to quantitative methods. It is useful to be reminded that the constructs of science, such as the categories of the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), are not direct representations of reality but rather imperfect maps always in need of revision. Therapists are well-advised to be sensitive to the cultural background of their patients, and, surely, all scientists need to be mindful of the social consequences of their work. This is particularly true in psychiatry, which has so much power over the lives and well-being of its patients.

BEHAVIORAL AND SOCIAL LEARNING APPROACHES

Theories of Personality

Behaviorism as a school of psychology grew up in reaction to the prevailing mentalistic model, in which introspection was used to determine the contents and operations of consciousness. John B. Watson (1878–1958) proposed that scientific psychology should confine itself to an examination of observable behavior and should explain all human conduct in terms of stimuli and learned responses. Ivan Petrovich Pavlov's (1849–1936) experiments with conditioned responses offered hope that such a science could be successful, and theorists such as Clark L. Hull (1884–1952) provided elaborate mathematical models of learning.

Radical Behaviorism. The most influential behaviorist and, perhaps, the most influential psychologist of the century was B. F. Skinner (1904–1990). Skinner's basic concept was operant conditioning, in which behaviors are viewed as a function of the organism's history of reinforcement. The observation that animals can be taught tricks by giving them rewards and punishments is nothing new. However, behaviorists, such as Skinner, refined and systematized this idea, using elegant experimental designs to tease apart the effects of the amount and schedule of reinforcements, the use of reinforcers and punishers, and the difficulty of the discriminations required. Behaviors could be shaped, maintained, or eliminated by the judicious use of these principles.

Skinner was a radical behaviorist, a purist who denied not only the scientific value but also even the existence of the mind. Furthermore, he avoided any neurophysiologic or psychophysiological theorizing, preferring to study the empty organism. Individual differences were ignored in understanding basic phenomena and were explained in individuals as the result of different histories of reinforcement. Even differences between species were neglected: Skinner believed that the pigeon provided an adequate model for the study of learning in all organisms, and he and his followers were, in fact, able to replicate many of their animal findings by using human subjects. Much of Skinner's success can be attributed to his single-minded pursuit of a highly circumscribed set of variables.

Skinner's view of personality was, predictably, a reductionistic one. As he stated in About Behaviorism, "a self or personality is at best a repertoire of behavior imparted by an organized set of contingencies. The behavior a young person acquires in the bosom of his family composes oneself; the behavior he acquires in, say, the armed services composes another." This position is rejected by humanistic psychologists, who attribute more choice and control to the individual, and by trait psychologists, who see consistencies of behavior that appear to transcend the consistencies of the reinforcing environment. Many personality psychologists have argued that controlled laboratory experimentation is a poor basis for theories of personality because individuals play a large role in selecting and shaping their own environments. Skinner's radical behaviorism was rejected or modified by many later learning theorists who acknowledged the power of conditioning but also recognized differences among species and among individuals within a species.

Social Learning Theory. One of the most distinctive features of human organisms is their use of speech, which makes possible elaborate thinking and planning and complex social interactions. In recent decades, learning theorists have increasingly emphasized social and cognitive processes. Among the most important have been Julian Rotter (1916–2014) and Albert Bandura (1925 to present), both of whom have offered versions of social learning theory.

Rotter's theory proposes that human behavior is guided not only by the actual history of reinforcement but also by plans, goals, and expectations of success. Individuals perform a behavior if they believe it is likely to lead to a valued goal, based on their past experiences in general and in similar situations. Individuals with a history of success are likely to have a generalized expectancy that they can control their lives; they are described as having an internal locus of control. At the opposite extreme are those whose prior efforts have been generally unsuccessful; they come to believe that rewards and punishments are a matter of luck or the arbitrary decisions of powerful others. Such individuals are said to have an external locus of control. Locus of control has been one of the most popular variables in personality research, used in numerous studies that generally are consistent with Rotter's theory.

Bandura's version of social learning theory also acknowledges the importance of internal cognitive processes. Individuals learn not only on the basis of their own experience but also through vicarious reinforcement from the observation of others. Bandura's demonstration of modeling effects in experiments conducted in the 1960s gave scientific legitimacy to the social learning perspective.

Rotter's and Bandura's theories are general theories of behavior, not specific theories of personality. However, for them, personality is something more than a collection of learned behaviors. The total pattern of experience leads to a generalized expectation of reinforcement or to a general sense of self-efficacy that can be considered the central individual difference variable. People are to be characterized primarily on the basis of their beliefs in their own ability to control their lives because these beliefs powerfully determine the effort they make to adapt to their surroundings.

Social-cognitive approaches to personality are among the most influential for current research in personality. These approaches focus on the individual's understanding of themselves and how these self-appraisals shape goals, plans, and behaviors. Because of their origins in social learning theory, they tend to emphasize the role of the environment, pointing out that an individual's sense of self varies from setting to setting. Because of their ties to social theory, they usually explain personality in terms of the effects of social interactions. For example, Hazel Markus (1949 to present) has suggested that individuals have a number of possible selves: Conceptions of what one is or could be, which result from the messages significant others provide. For such theorists, concern has moved beyond the social learning of specific behaviors to the learning of entire identities.

Theories of Psychopathology

Psychoanalytic theories of personality grew out of attempts to understand psychopathology, and there are thus intimate connections between the two. By contrast, behavioral approaches have focused on the general principles by which behavior is acquired and maintained, and psychopathology, where it is considered at all, is usually treated as an area of application. Learning theories have had much more influence on methods of psychotherapy than on theories of psychopathology itself.

Behavioral approaches might suggest two different classes of explanations for psychopathology: Psychopathology might be related to the mechanisms of learning themselves, or it might be considered the result of learned behaviors that are maladaptive or socially unacceptable.

In the 1950s, Hans Eysenck (1916–1997), a psychologist who has figured prominently in both learning and trait schools of personality, proposed that individual differences in the dimension of introversion versus extraversion determined the ease with which individuals could acquire conditioned responses, which in turn determined the form of psychopathology to which they were prone. Extremely introverted individuals, he proposed, were easily conditioned and thus acquired many inhibitions. They were predisposed to the development of depressive, anxious, and obsessive-compulsive disorders. By contrast, extreme extraverts were considered to be resistant to conditioning and were likely to develop hysterical and psychopathic disorders. (In later versions of Eysenck's theory, psychopathic disorders were grouped with psychotic disorders and linked to a different dimension of personality, psychoticism.)

Most behaviorists have viewed the laws of learning as universal processes and considered psychopathology to be the result of normal learning processes. In the 1920s, Irena Shenger-Krestovnika taught a dog to discriminate between a circle and an ellipse as a cue for food. When the ellipse was made increasingly circular, the dog's ability to discriminate between them was taxed, and the dog began to struggle, squeal, and bite. Pavlov dubbed this an experimental neurosis and proposed that human neuroses might have parallel causes.

Probably the most famous attempt to explain psychopathology in learning theory terms was provided by John Dollard (1900–1980) and Neal Miller (1909–2002). Dollard, an anthropologist, and Miller, an experimental psychologist, shared an interest in psychoanalysis. Their goal was to translate psychoanalytic concepts into the more testable terminology of learning theory. Consider, for example, the central psychoanalytic notion of repression. Parents might punish sexual behaviors in the child, and the child might learn to associate the behaviors with pain. By stimulus generalization, even the thought of the behaviors would elicit anxiety, and cognitive processes that blocked those thoughts would lessen anxiety and thus would be reinforced. Eventually, the thoughts would be effectively barred from consciousness.

Many behaviorists who did not share Dollard and Miller’s enthusiasm for psychoanalysis followed their lead in attempting to explain psychopathology in terms of principles of learning. Phobias, in particular, were easily explained as conditioned responses reinforced by avoidant behavior. Similarly, compulsions could be understood as a kind of self-reinforcing behavior: Each time the compulsive act is performed, the anxiety associated with not performing the act is reduced, increasing the probability that the behavior will be repeated.

Social learning theorists have also noted the self-perpetuating nature of some maladaptive behavior. Individuals who lack a strong sense of self-efficacy in social situations may avoid them. As a consequence, they fail to learn the social skills that would enhance their self-confidence. Self-defeating behaviors, which may appear irrational from an outside perspective, are often understandable in terms of the dynamics of learning.

Application of Theory to Therapy

Behaviorists have a rather rudimentary view of personality, seeing it as an assemblage of learned behaviors. They also tend to see psychopathology in superficial terms. Psychological maladjustment is considered to be the result of learned behaviors, which are called symptoms, but there is no underlying disorder of which they are symptomatic. Curing the symptoms cures the disorder. At worst, this position is naive and simplistic, equating the patient’s presenting problem with the real source of difficulty. At best, however, it focuses attention on a specific problem that can be concretely addressed.

A large number of techniques for behavior modification have been used with considerable success in treating symptoms of psychopathology. Joseph Wolpe (1915–1997) developed systematic desensitization as a treatment for phobias. Patients were instructed to relax and were then presented with increasingly vivid cues of the phobic object. Eventually, they were able to face the object itself without anxiety. A more dramatic technique is implosive therapy, in which the individual is confronted directly with the feared object (e.g., a room full of snakes) without an opportunity to escape. Because the object itself is harmless, and because avoidant behavior cannot be performed and is therefore not reinforced, the phobic reaction is swiftly extinguished.

Therapeutic interventions may be based on eliminating the reinforcements that sustain behavior, punishing unwanted behaviors, modeling or shaping more desirable behaviors, and so on. Any variable known to affect the acquisition or extinction of behaviors may provide an opportunity for behavior change, and behavioral techniques have been applied to physiologic responses, as well as voluntary behaviors, through techniques of biofeedback. Behavior therapies have been used extensively in treating phobias, controlling addictive behavior, reducing the self-destructive behavior of autistic children, and improving classroom discipline—for the behaviorist, the distinction between psychopathology and bad behavior is generally unimportant. Behavior therapies are most effective when the problem can be clearly traced to a particular set of behaviors or conditioned responses; they are much less effective in dealing with vague complaints of confusion and distress, although these are frequently the problems the patient presents to the clinician.

HUMANISTIC APPROACHES

Theories of Personality

Psychoanalysis and behaviorism are mechanistic theories that trace human behavior and experience to the gratification of instinctual impulses or to the acquisition of learned responses. Many of the most influential personality theorists have defined themselves in terms of their opposition to these two approaches. Although they vary widely in terms of the explanations they offer of personality, humanistic approaches share a positive evaluation of human nature and emphasize its unique and distinctively human aspects. Personality produces and reflects organization, rationality, consistency, future orientation, planfulness, self-expression, cognitive complexity, and adaptability. Most humanistic theorists prize human reason and freedom of will, the capacity for growth and change, the need for love, and self-transcendence. The positive psychology movement promoted by Martin Seligman (1942 to present) falls within this tradition.

Social learning theories might be seen as a humanized form of behaviorism because they recognize the role of complex symbolization and language in human learning. In a similar way, many now-classic humanistic theories were intended as modifications of psychoanalysis. Indeed, the first major psychoanalytic revisionist was Carl G. Jung (1875–1961), who argued that human beings had spiritual, as well as sexual, needs. Henry Murray (1893–1988) also made major modifications to psychoanalysis in his view of personality. For example, he credited the mature ego with much more autonomy than Freud granted it, and he argued that the individual's sense of morality was not fixed by the superego instilled in childhood but could continue to develop into more rational and altruistic forms. Erich Fromm (1900–1980) and Karen Horney (1885–1952) minimized the instinctual origin of personality development and suggested that culture played a large role in shaping the individual. Erik Erikson (1902–1994) proposed stages of psychosocial development to parallel Freud's psychosexual development, emphasizing such distinctly human characteristics as identity, intimacy, and generativity. He also theorized that personality development continued throughout the life span, giving encouragement to research on aging and personality.

Gordon Allport. Although he is usually classified as a trait psychologist, in his general orientation to theorizing, Gordon Allport (1897–1967) was clearly a humanist. For him, man's behavior is proactive, reflecting internal, self-initiating characteristics more than situational forces. In his view, human personality possesses psychological coherence and momentary (cross-sectional) and long-term (longitudinal) organization. Allport considered personality functioning to be characteristically rational, organized, and influenced by such conscious characteristics as long-range goals, plans of action, and philosophies of life.

Perhaps the most salient and controversial feature of his approach was the extreme emphasis that he put on the uniqueness of the individual personality. Allport viewed the major task of personology (or personality psychology) as the understanding and prediction of the individual case. Personal dispositions must be assessed to grasp the real personality, and this requires intensive study of an individual's past, present, and anticipated future functioning through the use of such techniques as the case history and content analysis of personal documents. In Becoming: Basic Considerations for a Psychology of Personality, Allport championed the view that concepts and laws must be developed to fit the individual case, creating the terms idiographic and morphogenic to symbolize his conviction that “each person is an idiom unto himself, an apparent violation of the syntax of the species.”

Allport was deeply concerned with identifying personality functions, which he discussed under the concept of the proprium, the superordinate concept in his system. Propriate functioning not only organized and integrated actions and experience but also provided the impetus to psychological growth. Allport described the functions of the proprium as a sense of body, self-identity, self-esteem, self-extension, rational coping, self-image, and propriate striving. These propriate functions were vital to personality, and, although they were ongoing, they were by no means considered unchanging. Allport theorized that the propriate functions are modified throughout life, predominantly in the direction of greater differentiation and integration or growth. The development of selfhood, away from the undifferentiated, opportunistic functioning of infancy and early childhood toward propriate functioning and striving, is part of human nature for Allport. The person guides or directs their life by attempting to fulfill their sense of self or proprium. Development continues into adulthood, with increasing signs of maturity and personal lifestyle.

Abraham Maslow. Abraham Maslow (1908–1970) interpreted personality in motivational terms. The individual’s whole life—their perceptions, values, strivings, and goals—is focused on the satisfaction of a set of needs, and the needs themselves are arranged in a universal hierarchy. Maslow’s needs serve an organizing and integrating role in life and are not to be understood as a simple and invariant set of responses to environmental pressures. They organize and create action possibilities and external reality.

At the lowest level of the motivational hierarchy are physiologic needs for food, water, sex, and sleep. The second level consists of safety needs, needs for protection, and security. The third level consists of needs for love and belongingness, and the fourth level consists of needs for self-respect and esteem from others. Above these lie the higher needs—for beauty, truth, justice, and self-actualization, the development of one’s full potential as a unique human being.

Individuals live at the lowest level of motivation which is problematic for them. That is, if needs for food and shelter are not routinely met, they become the overriding concern in life: The hungry individual risks danger and social ostracism to find food. Those who have always been well-fed, however, learn to take the satisfaction of physiologic needs for granted, and their attention is dominated by higher needs. Instead of examining specific behaviors and their reinforcements, Maslow's theory concerns the long-term satisfaction of broad classes of needs and thus gives a much broader depiction of the individual.

Maslow devoted much of his writing to a characterization of higher needs, including self-actualization, a drive to fulfill one's unique potential. He believed that personality psychology had become obsessed with psychopathology and that a corrective emphasis on positive mental health was needed. His biographical studies of such exemplary people as Eleanor Roosevelt and Abraham Lincoln suggested a number of distinctive characteristics of self-actualizers, including an accurate perception of reality, creativity, a need for privacy, and the frequent experience of mystical or peak experiences. As an exception to his general theory of motivation, he also noted that such individuals often skip the lower levels and proceed directly to self-actualization. The most creative artists and musicians never seemed to care about poverty or lack of social acceptance.

George Kelly. One of the most unconventional theories of personality was offered by George Kelly (1905–1967). It is, in some respects, a purely cognitive approach, but one with few ties to traditional learning theory. Instead of seeing them as organisms that are conditioned by their environment, Kelly argues that human beings should be seen as scientists trying to make sense of their world. In The Psychology of Personal Constructs, he states the fundamental postulate of his theory: "A person's processes are psychologically channelized by the ways in which he anticipates events."

The basic unit for understanding personality is the personal construct, a schema for classifying and interpreting experiences. For example, an individual might construe other people in terms of the contrast between strong versus weak. Each new acquaintance would be categorized as a strong or weak person, and subsequent interactions with this person would be guided by the original construal. In the course of experience, it would probably be necessary to reclassify some individuals initially thought to be strong as weak and vice versa; more importantly, some people might act in ways that were neither strong nor weak, leading the individual to develop new constructs (say, friendly vs. hostile) that were more useful in predicting other people's behavior.

This rather abstract and bloodless theory is made relevant to psychopathology by Kelly's ingenious reconstruals of some basic emotional reactions. He defines anxiety as the awareness that one's construct system is inadequate for construing important events. Guilt is the recognition that one's behavior is inconsistent with the ways in which one construes oneself. Hostility is viewed as the attempt to force experience to fit one's existing constructs. Such definitions are remote from common sense and clinical notions of anxiety, guilt, and hostility, but, precisely for that reason, they offer the prospect of novel ways of treating them.

Carl Rogers. Carl Rogers (1902–1987) is probably the most influential humanistic personality theorist. He articulated a formal theory of personality; pioneered a major school of therapy, client-centered therapy; and encouraged rigorous research on his theory and therapy. Rogers held that all organisms tend toward their own actualization—that mental health and personal growth are the natural condition of humankind. Psychopathology is a defensive distortion of this actualization process, and psychotherapy consists of creating conditions in which defense is unnecessary. Given these conditions, patients (or clients, as Rogers called them) essentially cure themselves.

Under ideal conditions, people's needs, desires, and goals emerge naturally as part of self-actualization and are recognized as part of the self; individuals are fully open to experience. In real life, however, one person's needs and desires often conflict with others' needs and desires; in particular, children find themselves in conflict with their parents, who withhold love when the child (from their perspective) misbehaves. Because love is so essential, children internalize these conditions of worth and believe that they are good and worthwhile individuals only when their self is consistent with the ideals imposed by significant others. To maintain their sense of worth, they may distort their experience; this leads to anxiety and self-defeating behavior.

In some respects, Rogers's theory is much like Freud's: Both see psychopathology as the result of defensive distortions and see the ideal state as one in which individuals can accept conflicts and deal with them rationally. Rogers is a humanistic theorist because he assumes that human nature is essentially good and that defenses are ultimately unnecessary. For Freud, the impulses of the id are eternally primitive and selfish, and their full actualization would be socially catastrophic.

Viktor Frankl. An Austrian neurologist and philosopher, Viktor Frankl's (1905–1997) distinctive view of human nature and psychopathology was profoundly shaped by his experience in Nazi concentration camps. There he came to the conclusion that even the most appalling circumstances could be endured if one found a way of making them meaningful. He described his experience in Man's Search for Meaning, a book that has been read by millions around the world.

Frankl was both a humanist and an existentialist. He believed that human beings shared with other animals somatic and psychological dimensions but that humans alone also had a spiritual dimension that confers both freedom and responsibility. People find meaning in their lives through creative and productive work, through an appreciation of the world and others, and by freely adopting positive attitudes even in the face of suffering. Those who fail to find meaning face alienation, despair, and existential neuroses. Traditional societies provided a framework of meaning in religion and shared cultural values; in modern society, people must find their own sources of meaning, and Frankl attributed many social problems, such as drug abuse and suicide, to their failures to do so.

Because of the spiritual dimension, human beings show self-transcendence and self-distancing. The former refers to the capacity to put other values (e.g., the well-being of a loved one) above self-interest. The latter is the ability to take an external perspective, as seen in a sense of humor. These capacities form the basis for therapeutic interventions in Frankl's version of psychotherapy known as logotherapy.

Dan McAdams. In the past three decades, a number of scholars in the humanities and social sciences have turned their attention to the life narrative as a focus of research. These writers argue that the consciousness of self that distinguishes human beings from other animals is not a static list of personal characteristics; it takes the form of a story. In telling their life stories, people explain themselves in the context of their history and their significant relationships. Life narratives are not objective life histories; they are subjective interpretations that give personal meaning to past, present, and future events.

The personality psychologist who is most closely associated with this perspective is Dan McAdams (1954 to present). McAdams postulated that personality could be understood on three levels: Level 1 consists of traits, abstract and enduring tendencies seen in general styles of action and experience. Level 2 is defined by personal concerns, the goals, plans, and strategies that preoccupy the individual at a certain time and place; later, McAdams adopted the term characteristic adaptations to describe a broader conception of this level. Level 3 is the life narrative, the story the person tells to themselves and to others in an effort to give a sense of unity and purpose to life. A common theme in America is the "redemptive self," in which the protagonist faces obstacles but eventually triumphs. Such a narrative appears to inspire a productive and caring life.

Psychiatrists and psychotherapists have, of course, been listening to patients' life stories for many decades, usually seeking clues to the origins of current problems. McAdams's approach is different; he wishes to understand the narratives as stories. Stories can be analyzed in terms of such features as narrative tone (e.g., tragic, comic, and ironic), imagery, theme (what goals the characters pursue), ideologic setting, and nuclear episodes (crises and turning points). From this perspective, key life events are not construed as causes of development but as symbols of identity. A patient's vivid recollection of a childhood humiliation may be important chiefly because it conveys the patient's sense of being a victim to whom fate has always been, and always will be, unfair.

Much of the scholarship on life narratives has been in a humanistic tradition that eschewed empirical rigor: a narrative reduced to a set of numbers is no longer a narrative. McAdams and his colleagues, however, have conducted psychometric studies on such basic issues as the inter-rater reliability and temporal stability of life story variables. These studies form the basis for a scientific evaluation of narrative perspectives on personality.

Theories of Psychopathology

In general, humanistic theories of personality stress positive aspects of human nature and discuss maladjustment in terms of failures and blocks to the full growth and development of the individual. It is of some interest to note that Rogers and Kelly formulated their theories in the context of counseling students—individuals who presumably had relatively minor maladjustments and considerable personality strengths. The applicability of humanistic theories to patients experiencing schizophrenia or dementia is certainly questionable, but the theories have had a profound effect on routine clinical practice, in which clearly diagnosable psychiatric disorders seldom account for all of the patient's problems in living.

Humanistic psychologists differ tremendously in their views on the origins of maladjustment. Rogers pointed to internalized conditions of worth acquired chiefly during childhood. Fromm, who was influenced by Marx, blamed society as a whole for instilling nonproductive orientations in individuals, such as hoarding or marketing orientations. Kelly said little about the origins of maladjustment but thought its essence was an ineffective construct system too rigid to be corrected by experience. Frankl believed some mental disorders were somatic or purely psychological in origin, but he also pointed to spiritual causes for the class of existential disorders.

Application of Theory to Therapy

Some humanistic theories of personality—for example, Allport's—have had little impact on psychotherapy; others, such as Rogers's, have been tremendously influential. It is helpful to recall that, for decades, the dominant form of therapy was psychoanalysis, a process that might require years and in which treatment was focused on dreams, childhood memories, and the ongoing relationship with the therapist (the transference) rather than on the immediate problems of the patient. Many of the standard techniques of contemporary counseling, clinical psychology, and psychiatry rest on a very different set of assumptions about human nature made scientifically respectable by the work of humanistic psychologists.

Brief psychotherapies often consist of opportunities for individuals to express their feelings and rethink their problems in a supportive atmosphere. The therapist may provide advice and guidance or at least may offer new ways in which patients can think about their problems. (Many psychiatrists use this general approach as an adjunct to medication, even in the treatment of serious mental disorders.) This process implicitly assumes that individuals, even those requiring psychotherapy, are basically rational and able, with some help, to solve their own problems; it also assumes that, given the right conditions, they move toward mental health: Patients are seen as scientists and self-actualizers.

Noting that Freud’s “psychoanalytic cure” was based on a conscious understanding of one’s life experiences, McAdams has argued that having a satisfying life narrative is a requirement for complete mental health. A good life story has coherence, credibility, a capacity for growth and change, and a generative orientation toward the world. One goal of psychotherapy, then, may be to help the patient rewrite their life narrative along these lines. Some (e.g., Sayer and colleagues) have claimed that writing about traumatic experiences has beneficial effects on mental and physical health, perhaps because the exercise of writing allows a rethinking of one’s life narrative.

Modifying a patient’s life story is a modest but, perhaps, realistic goal. Psychotherapists cannot easily alter patients’ personality traits, nor can they undo traumatic events of the past. They may, however, be able to help patients make sense of their dispositions and their life histories. Human tragedy can bring great suffering, but, in the hands of an artist, it can also be the source of great beauty. This was one of the major principles of Frankl’s logotherapy, in which patients were invited to examine their attitudes and reconstrue their suffering in ways that made its value apparent. A terminally ill woman who despaired that she would have to leave behind the children that she loved was asked if she would rather have been childless; that question allowed her to appreciate her life and legacy.

The most celebrated technique derived from logotherapy is the paradoxical intention, in which patients are invited to use their capacity for self-distancing to will what they fear or yield to their compulsions. A patient who stutters may be instructed to stutter as violently as possible; this reduces the pressure of trying not to stutter, and that, in turn, makes it possible to speak clearly. A number of behavioral techniques, such as implosive therapy, work on a similar principle of blocking a vicious circle of reinforcing undesirable behavior, but it is often difficult to convince patients to hazard the experiment. Frankl makes use of the characteristically human sense of humor to frame the paradoxical command in ways that motivate the patient.

The humanistic emphasis on freedom and responsibility has often clashed with the psychiatric tradition of regarding mental disorders as diseases. Labeling individuals as schizophrenics or phobics is held by some to be dehumanizing, and critics such as Thomas Szasz have argued that mental disorders are social and ethical judgments, not matters of medical fact. There is, of course, abundant evidence that some mental disorders have a biologic basis, but the criticisms of humanistic psychologists make the point that the disorder occurs in a human being who, in many respects, may be like any other person. There may be normal and abnormal behaviors, experiences, or relationships, but there are not normal and abnormal people.

TRAIT AND FACTOR MODELS

Individual differences are peripheral concerns in many social learning and humanistic theories of personality; they are the central focus of trait theories. The study of variations in human character and temperament goes back at least to Theophrastus (371–287 BCE), a Greek whose Characters depicted 30 different types. The morose type, for example, he described as follows:

A malignant temper sometimes vents itself chiefly in ferocity of language. The man whose tongue is thus at war with all the world, cannot reply to the simplest inquiry except by some such rejoinder as—“Trouble not me with your questions: Nor will he return a civil salutation…. He has no pardon for those who may unwittingly shove or jostle him, or tread upon his toe… He will neither wait for nor stay with anyone long: Nor will he sing, or recite verses, or dance in company. It is a man of this spirit who dares to live without offering supplications to heaven.”

Theories of Personality

The scientific study of individual differences in personality can be traced to Sir Francis Galton (1822–1911) in England, who laid the foundations of psychometrics, and to Gerard Heymans (1857–1930) in the Netherlands, who undertook the first large-scale study of rated personality traits. The first major trait theorist in the United States was Gordon Allport, whose 1937 volume, Personality: A Psychological Interpretation, spelled out the basic issues in trait psychology. He defined a trait as “a neuropsychic structure having the capacity to render many stimuli functionally equivalent, and to initiate and guide equivalent (meaningfully consistent) forms of adaptive and expressive behavior.” In this view, something in the brain of the morose man makes him see even simple questions or greetings as a personal affront, and his sullen attitude is expressed in a variety of social situations.

Allport believed that traits were concrete features of individuals that uniquely described them and that might be understood by a case study of a single individual. A contrasting view is that traits are dimensions of individual difference that can only be discovered by comparing and contrasting different individuals; individuals are then described in terms of their standing on a set of common traits. The two definitions are closely related; people who are more anxious than 99% of the population have, presumably, a neuropsychic structure that makes them so anxious.

Characteristics of Traits. Although there are many different trait theories, there is general agreement on several key features of traits: (1) Traits are tendencies to show consistent patterns of thoughts, feelings, and actions. Behaviors that are specific to a single setting or situation may better be considered habits than traits; some evidence of cross-situational consistency is necessary to infer a trait. However, concrete instances of behavior have many determinants, including learned habits, aroused needs, social contexts, role requirements, and the influence of many different and potentially conflicting traits, so the influence of a specific trait on any particular behavior may be quite modest. It is usually only by viewing behavior across many different situations that a consistent pattern can be detected. (2) Traits are relatively enduring features that characterize the individual. In this respect, they are to be distinguished from transient moods or episodes of mental disorders that affect the individual. The fact that traits are relatively enduring does not mean that they cannot change; traits are not immutable, even if they are durable. (3) Traits are continuously distributed, usually approximating a normal or bell curve. Although it is convenient to speak about introverts and extroverts, in fact, most individuals are ambiverts, showing some of the characteristics of introverts and some of the characteristics of extroverts. There is no consistent evidence of discrete personality types.

From time to time, there has been controversy over the reality of traits, fueled by the fact that human beings easily and readily ascribe traits to others on the basis of little or no information, with correspondingly limited accuracy. These personality ascriptions may be triggered by stereotypes of age or physical appearance or may be quite idiosyncratic. Demonstrations of this fact in laboratory experiments by social psychologists, together with the relatively loose cross-situational consistency of most traits, led a generation of psychologists in the 1970s to conclude that traits were cognitive fictions. Subsequent work—particularly, demonstrations that judges who knew the individual well agreed with one another and with the self-reports of the individual about their standing on a variety of traits—restored faith in the consensual validity of traits. However, the controversy does make the crucial point that some trait ascriptions are more accurate than others and that first impression may be quite misleading. Psychiatrists ought not to assume that their clinical judgments of a patient's personality are correct; validated personality questionnaires and rating forms completed by knowledgeable others may be needed to portray and understand personality accurately.

Personality Structure and Factor Analysis. The most important differences among trait theorists are in the specific traits that they have conceptualized and measured. Jung identified introversion and extraversion as basic personality variables, Bandura emphasized self-efficacy, and Rogers was concerned with openness to experience. Over the years, literally, thousands of scales have been developed to measure traits that psychologists considered important in understanding personality. As early as 1936, Allport pointed to another source for identifying personality traits: The natural language. In a monograph he published with Henry Odbert, he listed some 18,000 terms extracted from an unabridged dictionary that could be used to describe people; some of them were mere evaluations (e.g., swell and awful), but he regarded approximately 4,000 as legitimate trait terms.

The problem for trait psychologists was how to choose a manageable set of traits from among the many possible constructs. It was obvious that trait terms were highly redundant—for example, anxious, worrying, nervous, apprehensive, and fearful reflect similar, if not identical, characteristics—so what was needed was a procedure for identifying major groups of traits that covaried. Factor analysis, a statistical technique that reduces the complexity of a set of correlations among variables, was first used in personality research by J. P. Guilford (1897–1987) and has remained one of its basic tools. The factors or dimensions identified in this process correspond to groups of closely related traits; the set of basic dimensions identified by the factor analysis constitutes a model of the structure of personality traits.

Raymond Cattell (1905–1998) developed one of the first and most influential factor models. He reasoned that, in the course of cultural evolution, any personality trait important in human social interaction would have been noticed and named; the 4,000 trait terms identified by Allport and Odbert could thus be assumed to represent an exhaustive listing of personality characteristics (this has become known as the lexical hypothesis). Cattell grouped synonyms and near-synonyms together to obtain a set of 35 personality variables and asked respondents to rate acquaintances on each of these sets of terms. He intercorrelated the ratings and factored the correlations, identifying 12 factors. Together with four more factors found in research using self-report questionnaires, these became the basis for the 16 Personality Factor Questionnaire (16PF), a self-report instrument that has been widely used in personality research and clinical psychology for more than 50 years.

It was originally hoped that factor analysis would provide an objective solution to the question of personality structure, but for many years there was little agreement among factor analysts. Eysenck believed that Cattell's model could not be replicated and was needlessly complex. He proposed a simple and powerful two-dimensional model that identified extraversion–introversion (E) and neuroticism–emotional stability (N) as superfactors and showed that, if the scales of the 16PF were themselves factored, the two largest factors resembled his E and N. He and his wife, Sybil Eysenck (1927 to present), developed a series of instruments to measure these factors (and, later, a third superfactor called psychoticism) that has also been widely used, particularly in Great Britain. Eysenck's stature as a learning theorist and a critic of psychoanalysis contributed to the importance of these dimensions in psychiatric contexts.

Five-Factor Model. Eysenck's two factors were widely replicated, but they seemed to omit many important characteristics, such as curiosity, aggression, and achievement striving. An alternative solution was offered in 1961 by two U.S. Air Force psychologists, Ernest Tupes and Raymond Christal. They began with the 35 clusters of traits identified by Cattell and obtained ratings on these clusters in eight different samples. They found that a five-factor solution fit the data in all eight samples. Two of the factors resembled Eysenck's E and N, but three other factors were new.

A small group of lexical researchers, including Warren Norman (1930–1998) and Lewis R. Goldberg (1931 to present), continued to study personality structure as represented by natural language trait adjectives, and, after 20 years, they came to the conclusion that the five-factor structure proposed by Tupes and Christal was essentially correct. Renewed interest in this model showed that the five factors could be recovered in analyses of self-reports and observer ratings; in ratings of children, college students, and older adults; and in several different languages, including non–Indo-European languages, such as Chinese, Hebrew, and Filipino. The factors appeared in analyses of trait adjectives, descriptive phrases, and questionnaire scales. Contemporary five-factor researchers differ somewhat in their conceptualizations of the factors and consequently give them somewhat different labels. The terms neuroticism (N), extraversion (E), openness to experience (O), agreeableness (A), and conscientiousness (C) are used here. The five factors and some of the traits, or facets, that define them are given in Table 6.4–1, along with associated adjectives.

Many psychologists were skeptical of the lexical hypothesis that had led to the FFM. These critics believed that personality theory and clinical experience would lead to the identification of important traits for which no lay terms existed, and they continued to offer alternative models. Katharine Briggs (1875–1968) and Isabel Myers (1897–1980) operationalized Jung's psychological functions in the Myers–Briggs Type Indicator, which classifies individuals in terms of the dichotomies of introversion versus extraversion, intuition versus sensing, thinking versus feeling, and judging versus perceiving. Some (e.g., Jerry S. Wiggins, 1931–2006) have argued that the traits that influence social interactions were better represented in a circular order than as a set of factors, and many instruments have been developed to measure this model.

A particularly important system was suggested by Theodore Millon (1928–2014), who was interested in personality traits associated with psychiatric disorders. His reviews of clinical literature led to a theory of personality and psychopathology that specified 11 personality disorders as extreme variants of normal traits. For example, the histrionic personality disorder is supposed to be related to the trait of gregariousness; the schizoid personality disorder is related to the trait of detachment. Millon's theory had a profound impact on the formulation of Axis II in the third edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III) and in subsequent editions. His instrument, the Millon Clinical Multiaxial Inventory, has been widely used by psychiatrists and clinical psychologists.

The fact that trait theories of personality are usually tied to assessment inventories makes it relatively easy to make empirical comparisons, and, in the last decade, researchers in several countries have undertaken the task of relating different trait models. There is a growing consensus among these researchers that virtually all the traits measured by theory-based personality questionnaires—including those derived from psychodynamic, behavioral, and humanistic theories—are related to one or more of the five factors of Tupes and Christal. However, instruments vary in comprehensiveness. For example, the four scales of the Myers–Briggs Type Indicator correspond to four of the five factors, whereas measures of the interpersonal circumplex represent only two factors (extraversion and agreeableness).

These comparisons of instruments can lead to significant reconceptualizations. For example, Cloninger's Temperament and Character Inventory (TCI) consists of four factors that are intended to assess temperament and three that assess character. However, joint analysis with a measure of the FFM shows that the Harm Avoidance temperament scales and the Self-Directedness character scales are really opposite poles of a single neuroticism factor, whereas the Reward Dependence temperament scales and the Cooperation character scales are both measures of agreeableness. From the perspective of the FFM, the Temperament and Character Inventory's distinction between temperament and character appears not to be supported.

At the broadest level, then, the problem of personality structure appears to have been resolved: Personality is described by five basic factors. This does not mean that personality can be exhaustively described by standing on five dimensions. Most trait psychologists adopt hierarchical models of trait structure. They assume that the broadest factors are composed of more specific traits, which, in turn, are defined by subtraits that correspond to individual items in a questionnaire. In the NEO Personality Inventory 3 (NEO-PI-3), for example, six specific traits or facets are measured for each of the five factors (or domains) of personality. The facet scales are listed in Table 6.4–1; the hierarchical organization is illustrated in Figure 6.4–1.

Assessment on the level of specific facets provides a more detailed and personalized portrait of the individual.

Origin and Development of Personality Traits. Psychoanalytic, learning and humanistic theories have usually offered causal explanations for individual differences. Thus, differences in self-efficacy are supposed to be caused by different histories of success in pursuing goals; variations in openness to experience might be the result of differences in the conditions of worth imposed by parents. The factor analysts who scoured the dictionary for trait terms usually bypassed this issue, being content to describe the personality differences they found in adults. In principle, some traits might be inherited, some might be instilled by parents, and some might be learned from experience; whatever their origin, they could be measured and used to predict important life criteria.

Until recently, it was generally assumed that personality was shaped primarily by a variety of environmental influences, including parental love and discipline, social and economic opportunities, and life experiences through childhood and adolescence. Surprisingly, this assumption has rarely been tested: There has been little prospective longitudinal research documenting links between early childhood experiences and subsequent adult personality. A different research design, using the techniques of behavior genetics, can answer these questions by comparing personality measures in adults with different degrees of genetic and environmental similarity. For example, the similarity between identical twins reared apart can be attributed to genetic influences, whereas the similarity between adopted siblings reared together must be due to shared environmental influences.

Since the early 1980s, behavior genetics studies using many different samples, personality measures, and methods of data analysis have converged on the surprising conclusion that personality traits are, to a considerable extent, heritable, and, to a considerable extent, due to unknown and idiosyncratic causes. The molecular genetics underlying trait heritability has been a topic of great interest in the past few years, but research approaches are still being refined. Early studies claiming to find single genes for major traits are giving way to newer paradigms. These more sophisticated approaches use combinations of traits to define personality styles or patterns that better define the personality phenotypes for genetic linkage and association studies.

Less success has been found in identifying the environmental origins of personality traits. In fact, they are hardly attributable to shared environmental causes at all. Socioeconomic status, family diet, religious training, parental modeling, and all the other influences that children growing up in the same household would normally share seem to have little or no influence on adult personality. This conclusion applies as much to character traits, such as achievement striving and modesty, as to temperament traits, such as anxiety and energy level. This dramatic and counterintuitive finding will doubtless reshape theories of personality. As Sandra Scarr (1936 to present) commented, “psychology [currently] has no adequate theories to account for individual variation in behavior because our theories address the wrong sources of variation.”

Table 6.4–1.

Five Factors of Personality, Defining Traits, and Empirically Associated Adjectives

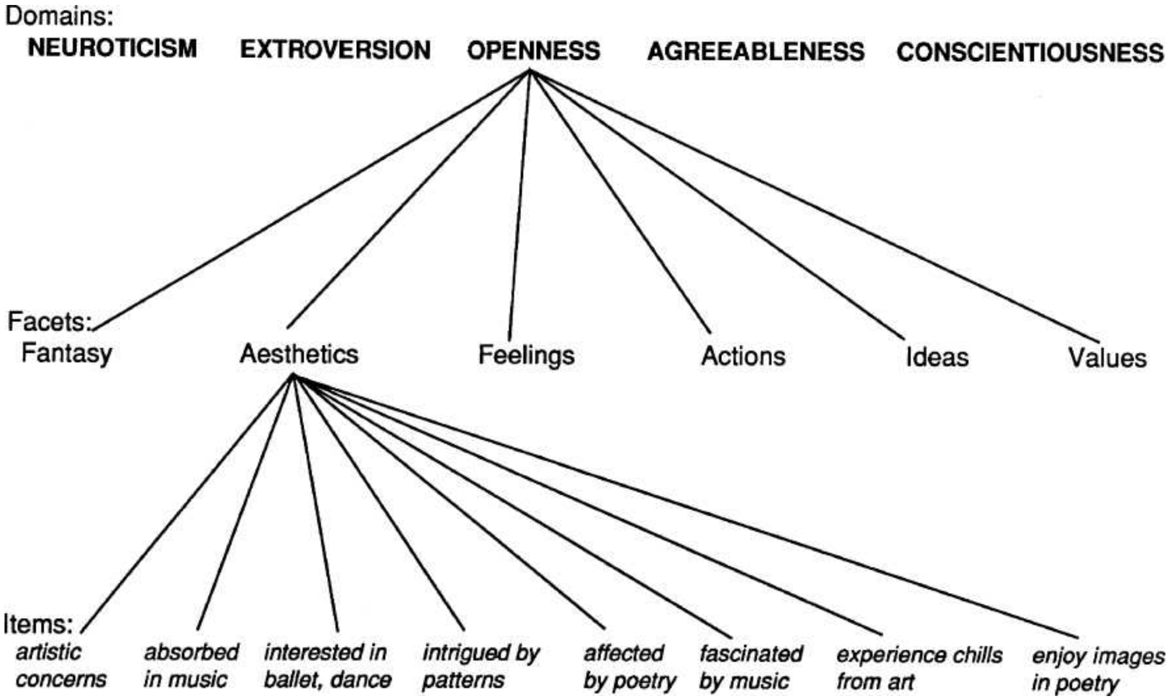
Factor	Trait	Adjectives
Neuroticism (N)	Anxiety	Anxious, fearful, worrying, tense
	Angry hostility	Irritable, impatient, moody, not gentle
	Depression	Pessimistic, worrying, not contented, moody
	Self-consciousness	Shy, not self-confident, timid, inhibited
	Impulsiveness	Hasty, self-centered, excitable, loud
	Vulnerability	Not confident, not efficient, not clear-thinking, anxious
Extraversion (E)	Warmth	Friendly, warm, sociable, not aloof
	Gregariousness	Sociable, outgoing, talkative, not withdrawn
	Assertiveness	Assertive, forceful, aggressive, confident
	Activity	Energetic, hurried, quick, active
	Excitement seeking	Pleasure-seeking, adventurous, daring, spunky
	Positive emotions	Enthusiastic, humorous, optimistic, jolly
Openness (O)	Fantasy	Dreamy, imaginative, artistic, complicated
	Aesthetics	Artistic, original, inventive, idealistic
	Feelings	Excitable, spontaneous, affectionate, insightful
	Actions	Wide interests, versatile, adventurous, imaginative

	Ideas	Curious, original, insightful, inventive
	Values	Not conservative, not cautious, flirtatious, unconventional
Agreeableness (A)	Trust	Trusting, not suspicious, forgiving, not wary
	Straightforwardness	Not shrewd, not autocratic, not charming, not demanding
	Altruism	Soft-hearted, gentle, generous, kind
	Compliance	Not stubborn, not demanding, not headstrong, not impatient
	Modesty	Not a show-off, not clever, not argumentative, not self-confident
	Tender-mindedness	Sympathetic, soft-hearted, warm, kind
Conscientiousness (C)	Competence	Efficient, thorough, resourceful, intelligent
	Order	Organized, precise, methodical, thorough
	Dutifulness	Thorough, not careless, not distractible, not lazy
	Achievement striving	Ambitious, industrious, enterprising, persistent
	Self-discipline	Energetic, not lazy, organized, not absent-minded
	Deliberation	Not hasty, not impulsive, not careless, not immature

Adjectives are significantly correlated with traits, *N* = 305; *P* < .001.

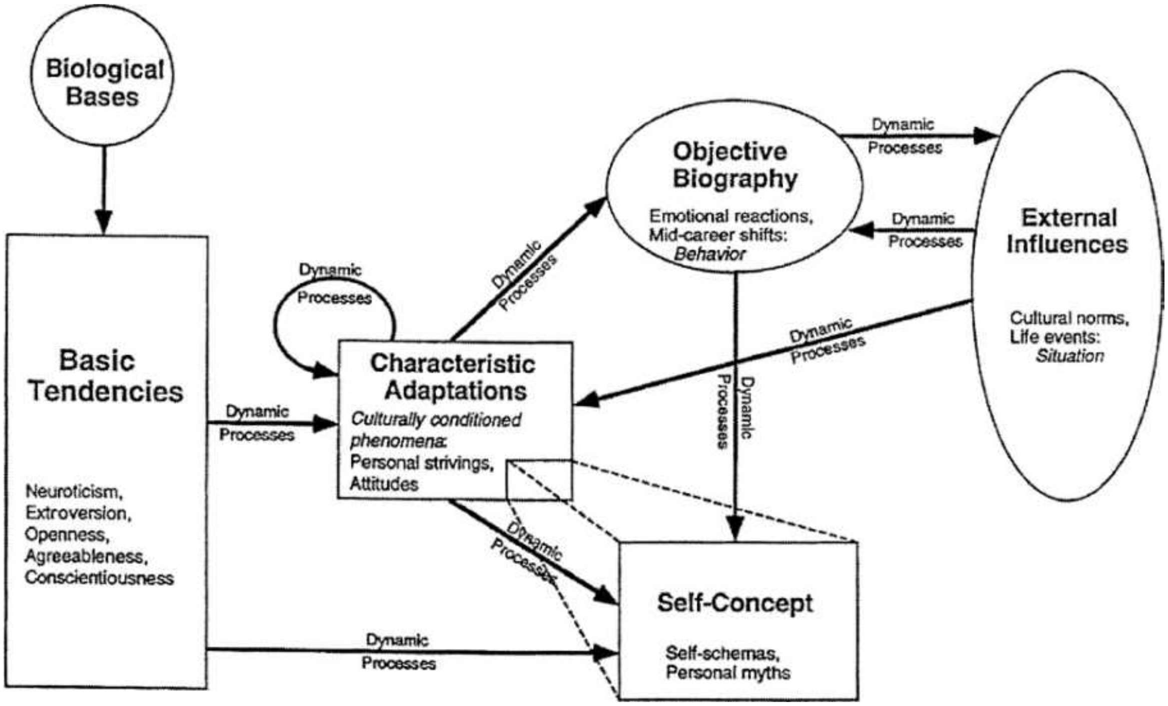
Adapted from McCrae RR, Costa PT Jr. Discriminant validity of NEO-PI-R facet scales. *Ed Psychol Meas*. 1992;52(1):229. doi: 10.1177/001316449205200.

One new theory that does begin to address the “right” sources of variation is the five-factor theory. This theory attempts to provide a conceptual framework in which the body of research on the FFM can be interpreted. The five-factor theory is a systems theory, represented schematically in Figure 6.4–2. The central components are basic tendencies (including personality traits and intelligence, and other abilities) and characteristic adaptations (such as skills, attitudes, values, and roles). In this model, as suggested by behavioral genetics, the only input to basic tendencies is from biologic bases. However, personality traits and external influences are important in shaping characteristic adaptations. For example, an individual who is temperamentally high in self-consciousness and who repeatedly experienced ridicule as a child might develop an avoidant personality disorder, which is a characteristic (mal)adaptation.



Domains:
NEUROTICISM
EXTROVERSION
OPENNESS
AGREEABLENESS
CONSCIENTIOUSNESS
Facets:
Fantasy
Aesthetics
Feelings
Actions
Ideas
Values
Items:
artistic concerns
absorbed in music
interested in ballet, dance
intrigued by patterns
affected by poetry
fascinated by music
experience chills from art
enjoy images in poetry

FIGURE 6.4–1. An example of hierarchical organization in the Revised NEO Personality Inventory: domains, facets of openness, and items measuring openness to aesthetics.



Biological Bases
Basic Tendencies
Neuroticism, Extroversion, Openness, Agreeableness, Conscientiousness
Dynamic Processes
Characteristic Adaptations
Culturally conditioned phenomena: Personal strivings, Attitudes
Objective Biography
Emotional reactions, Mid-career shifts: Behavior
External Influences
Cultural norms, Life events: Situation
Self-Concept
Self-schemas, Personal myths

FIGURE 6.4–2. A representation of the personality system as depicted by the five-factor theory. The ellipses represent peripheral elements, and the rectangles represent central elements. Examples of content are given in each. Arrows indicate the direction of causal influences. (Reprinted with permission of Guilford Publications. McCrae RR, Costa PT Jr. A five-factor theory of personality. In: Pervin LA, John OP, eds. *Handbook of Personality: Theory and Research*. 2nd ed. 1999:139. Adapted with permission from Costa PT Jr, McCrae RR. Set like plaster? Evidence for the stability of adult personality. In: Heatherton TF, Weinberger JL, eds. *Can Personality Change?* American Psychological Association; 1994:24. Copyright © 1994 by American Psychological Association.)

For many years developmental psychologists assumed that personality development ended with adolescence. A 21-year-old is legally an adult and is unlikely to grow much in physical height or intellectual capacity, but recent research has shown consistent changes in personality between college age and middle adulthood. There is a dramatic decline in excitement seeking over that interval, but, in addition, cross-sectional and longitudinal studies of American college students have shown that of the five-factor traits, N, E, and O decline during the decade of the 20s, whereas A and C increase. As a result, 30-year-olds are less emotional and better socialized than 20-year-olds.

There is reason to believe that these changes are not the product of the relatively indulgent American experience of adolescence. The same pattern of age differences is seen in less-affluent countries, such as Croatia, and in non-Western countries, such as South Korea. Such cross-cultural studies suggest that there may be intrinsic maturational processes in personality development, which is consistent with the biologic basis of personality traits hypothesized by the five-factor theory.

There have also been important developments in understanding personality change in individuals older than 30 years of age. Traits are defined as relatively enduring patterns of behavior, but most psychologists assumed that traits would be modified by life experiences. Jung postulated that the process of individuation required each individual to express all of their potentials, and, thus, the young introvert would normally become an extravert in old age, and vice versa. Lay stereotypes of aging held that, as they age, people become cranky, conservative, and depressed. Gerontologists rebutted these myths of aging, arguing that old age was more likely to bring maturity, wisdom, or detachment. Theories of adult development, popularized in Gail Sheehy's best-selling Passages, suggested that personality changed in stages and, in particular, that men (and perhaps women) went through a midlife crisis in their 30s or 40s.

In sharp contrast to all these theories are the findings from a number of independent longitudinal studies of personality in adulthood. These studies present a clear picture of predominant stability of the full range of personality traits. Although there are very gradual changes in the mean levels of traits across adulthood, individuals tend to maintain the same rank order. The 30-year-old, who is outgoing, curious, and hardworking, is likely to become an outgoing, curious, and hardworking 80-year-old. This conclusion has been supported by studies using self-reports and observer ratings of all five factors of personality and appears to apply to men and women. Of course, there are often dramatic changes in personality as a result of dementing disorders in old age, but normal life experience seems to have little impact on personality in individuals older than 30 years of age.

There are distressingly little data on the long-term effects of psychopathology on personality. Individuals in recovery from an episode of major depressive disorder generally score high on measures of the five-factor trait N, and it is sometimes argued that this is a result of the experience of depression. However, the few prospective studies of the first onset of major depression typically show that these individuals scored high on N before the first episode, suggesting that high N may be an enduring feature of people prone to clinical depression.

Theories of Psychopathology

The links between psychopathology and trait psychology are at once intimate and complex. For decades, psychiatrists and clinical psychologists have administered psychological tests such as the Minnesota Multiphasic Personality Inventory (MMPI) and Cattell's measure of personality, the 16PF, to inform the diagnosis of mental disorders; these same tests have been used routinely by trait psychologists to examine relations between personality and such criteria as vocational preference, creative potential, and coping with life stress. The dividing line between normal variations in personality dispositions and psychopathology is frequently unclear.

This poses more of a problem to psychiatric nosology than it does to trait theories of personality. Psychiatric diagnoses are supposed to represent the presence of a discrete disorder, and the DSM-5 specifies the criteria that must be met to confer each diagnosis. This categorical model is appropriate for some disorders but not others. It may be difficult to separate social phobia, for example, from extreme shyness and self-consciousness or a schizoid personality disorder from marked introversion. This is entirely consistent with trait models of personality, which regard individual differences as continuously distributed variables.

Neuroticism and Psychopathology. One theory of psychopathology, therefore, is that some psychiatric disorders reflect extreme standing on personality traits, particularly those related to the five-factor trait N. Among the traits that covary in normal populations to define this factor are predispositions to experience chronic levels of negative affects, such as fear, anger, shame, and sadness. Individuals with high standing on these traits may qualify for a diagnosis of generalized anxiety disorder, borderline personality disorder, social phobia, or dysthymia.

The five-factor trait N may also be considered a risk factor for the development of psychiatric disorders that are not themselves trait-like. Several recent studies have demonstrated that individuals scoring high on measures of N are at increased risk of subsequently receiving a diagnosis of major depressive disorder. Poor control of urges and impulses and excessive concern with physical functioning are also characteristics associated with N, and it might be hypothesized that individuals high in N are predisposed to develop eating disorders and hypochondriasis. N is, in essence, a generalized disposition to experience psychological distress, and individuals seeking psychiatric treatment are almost always distressed. It is therefore not surprising that virtually all clinical populations, from drug abusers to schizophrenics, score high on measures of N.

Historically, the term neurosis or psychoneurosis was coined to identify psychiatric disorders of functional origin that were closely related to anxiety and its control. It survived in the revised third edition of DSM (DSM-III-R) in many secondary labels (dysthymia, e.g., was also called depressive neurosis) but is not used in subsequent editions. Many personality psychologists object to the term neuroticism as a label for a dimension of normal personality because of its suggestion of psychopathology. Many psychiatrists object to the term because it appears tied to an outdated psychiatric nosology. However, the term serves a useful purpose: It is a reminder to clinicians that patients with a wide variety of diagnoses share many features related to chronic psychological distress and is also a reminder to personality psychologists that the difference between normal and abnormal functioning is often only one of degree.

Maladaptive Styles. Shapiro’s (1999) classic book on neurotic styles offered an extremely useful perspective for understanding the differences between normal and abnormal personalities. The clinical value of Shapiro’s approach is its integrative perspective on functioning that recognizes a multiplicity of factors, both adaptive and maladaptive, that operate in peoples’ lives to produce a distinctive style of psychological functioning that provides direction and consistency in behavior. Schapiro’s approach is insightful and rich in clinical detail. While the FFM and FFT were not around when Shapiro developed his ideas, the FFM can nonetheless provide a useful interpretive paradigm for understanding how the expression of various personality trait combinations contribute to maladaptive styles of functioning and impairments in various spheres of life. The NEO Style Graphs can provide insight into some of the ways people act in different aspects of life. These circumplexical style graphs are formed by the intersection of the two factors and are divided into four quadrants (e.g., +/ –; +/ +; –/+; and –/–). There are ten combinations of the five broad personality factors that describe an individual’s styles of Well Being, Defense, Anger Control, Impulse Control, Interests, Interactions, Activity Attitudes, Learning, and Character. Relevant to Shapiro’s neurotic styles, we will consider only the four maladaptive styles of Well-Being (N+ by E–) Defense (N+ by O–), Anger Control (N + by A–), Impulse Control (N+ by C–).

The high N and Low E combination represents the “Gloomy Pessimist” aspect of the Style of Well-Being. Such individuals, because of their high distress proneness and low positive affect or energy, face a dark and dreary life with few things that cheer them and many that cause anguish and distress. Stressful circumstances often lead them to feeling depressed. Even under normal circumstances, they often find life hard and joyless. These are individuals who feel no positive affect and believe that life holds little value or happiness for them. Such individuals may experience a number of existential crises, including a diminished sense of personal worth and value, a lack of personal meaning, and a belief that the future holds no solutions or opportunities for improvement. Further compounding their situation is the lack of a useful social support network to provide emotional care. These individuals are frequently loners who are detached from their environments and are prone to experience deep loneliness. These individuals should not be confused with schizoid personality disorder; such individuals may be aloof and detached from social interactions, but that is their preferred style. The high N and low E person are isolated and detached not because of preference, but rather because they are overwhelmed with feelings of inadequacy and emotional distress and are fearful of social criticism. They may also lack the social tools and skills necessary to effect any positive coping with their situation.

The high N and Low O combination defines the “Maladaptive” type of defense style. These individuals tend to use primitive and ineffective defenses such as repression, denial, and reaction formation. They prefer not to think about disturbing ideas, and they may refuse to acknowledge possible dangers (such as a serious illness). They lack insight into the distressing affects they experience, and because they cannot verbalize their feelings, they may be considered alexithymic. The low O may also create a more authoritarian orientation toward life, believing that there are clear rules and guidelines that define and determine appropriate intra- and interpersonal processes. Securely settled within their own acquired belief structures, such individuals may be unable to adjust or adapt their behaviors in ways that facilitate their engagement with others. Thus, they may easily put off others and develop feelings of alienation and isolation.

Style of anger control considers levels of N and Agreeableness (A). While Extraversion examines our interest in being with others and our level of engagement with them, A relates to the quality of our interactions with others, ranging from a very compassionate, caring, and altruistic orientation to a more antagonistic, selfish, and manipulative style. The presence of high N serves to attenuate the communal, bonding aspects of the highly agreeable person while exacerbating the hostile, confrontational aspects of the antagonistic individual. The style involving high levels of N with low levels of A is termed “Temperamental.” These individuals are easily angered and tend to express anger directly. They may fly into a rage over a minor irritant, and they can seethe with anger for long periods of time. They are deeply involved in themselves and take offense readily, and they often overlook the effects of their anger on others. They may be prone to physical aggression and verbal abuse. Because these individuals may possess feelings of personal inadequacy and have a tenuous hold on their life tasks, they are keenly sensitive to any criticism or negative evaluation of their behavior, seeing them as threats that may expose them as impostors or worse. They respond quickly and harshly to any accusations of personal worth and are willing to physically strike out against any external agency.

The fourth and final maladaptive style relates to the role of Conscientiousness in moderating the expression of negative affect influencing self-regulation, which is the impulse control style. High levels of C are associated with good self-control, including active processes of planning, organizing, and carrying out tasks. Low levels of C are related to a more “here and now” orientation, a desire to take the path of least resistance, and a goal to maximize hedonic pleasure. For those who are low on C, their manner of impulse control is labeled “Undercontrolled.” These individuals are often at the mercy of their own impulses. They find it difficult and distressing to resist any urge or desire, and they lack the self-control to hold their urges in check. As a result, they may act in ways that they know are not in their long-term best interests. They may be particularly susceptible to substance abuse and other health risk behaviors. These individuals are very hedonistically oriented, preferring immediate pleasure to long-range success. These individuals frequently end up disappointing others in their lives because of their inability to live up to their commitments and obligations. Further complicating their relationships with others is underlying selfishness to their strivings. Others are valued and useful primarily to the extent that they can provide for whatever physical and/or emotional needs they may have. Undercontrolled style people are not necessarily manipulative in their manner of relating to others so much as they are interested in fulfilling their personal algorithm of obtaining maximum benefit for minimum effort or investment.

The above style descriptions represent only a fraction of available possibilities. McCrae and Costa (2010) provide more detailed descriptions for every quadrant in the 10 Style Graphs.

Personality Traits and Personality Disorders. DSM-5 provides a general definition of a personality disorder that applies to all 10 of the specific disorders: “A personality disorder is an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual’s culture, is pervasive and inflexible, has an onset in adolescence and early adulthood, is stable in time, and leads to distress or impairment.” (p. 645)

It is reasonable to ask whether these inflexible and maladaptive traits are the same as or different from those encountered in nonpsychiatric populations. Several recent studies on this question have concurred in finding strong and replicable links between scales measuring personality disorders and the five factors in normal and clinical populations.

In the case of N, only high scores are associated with psychiatric impairment, but both poles of the other factors appear to be associated with specific forms of psychopathology. Individuals high in E tend to have histrionic and narcissistic personality disorders; those who are low in E have avoidant and schizoid disorders. High C is associated with obsessive-compulsive personality disorder; low C is associated with antisocial personality disorder. Low A, or antagonism, is characteristic of individuals with paranoid, antisocial, and narcissistic personality disorders. High A is associated with dependent personality disorder.

FFM Descriptions of Personality Disorders. Thomas Widiger and colleagues have linked the personality disorders with FFM traits. In one study, the diagnostic criteria and text descriptions of each personality disorder were coded in terms of the 60 poles of the 30 facets of the FFM (see Table 6.4–1). In other studies, personality disorder researchers and practicing clinicians were asked to describe a prototypic case of each of the ten personality disorders using the negative and positive poles of the 30 facets of the FFM. Table 6.4–2 presents an integrative summary of these FFM descriptions.

These associations show some of the ways in which disorders can be conceptually distinguished. For example, avoidant and schizoid personality disorders are both characterized by low gregariousness, but only the former shows associations with high anxiety, depression, self-consciousness, and vulnerability. Research in several countries has generally supported this mapping of disorders onto personality traits, although the conceptual distinctions highlighted in Table 6.4–2 are usually blurred in real data because of the pervasive comorbidity of personality disorders.

It is a matter of current controversy just how these personality traits are related to the disorders: Are normal personality traits carried to an extreme inherently maladaptive, or do these traits merely predispose individuals to develop disorders under certain circumstances? Some research has also called into question the meaningfulness of the syndromes recognized by DSM-5 by showing that the symptoms used to define the disorders, when separately assessed, do not covary in ways that match the DSM-5 syndromes. Instead, the symptom clusters that do emerge are interpretable in terms of the FFM. As a result of such evidence, proposals have been made to replace the current categorical model with dimensional models that relate problems in adjustment to standing on basic dimensions of personality. This would appear to be a logical extension of trait theories of psychopathology.

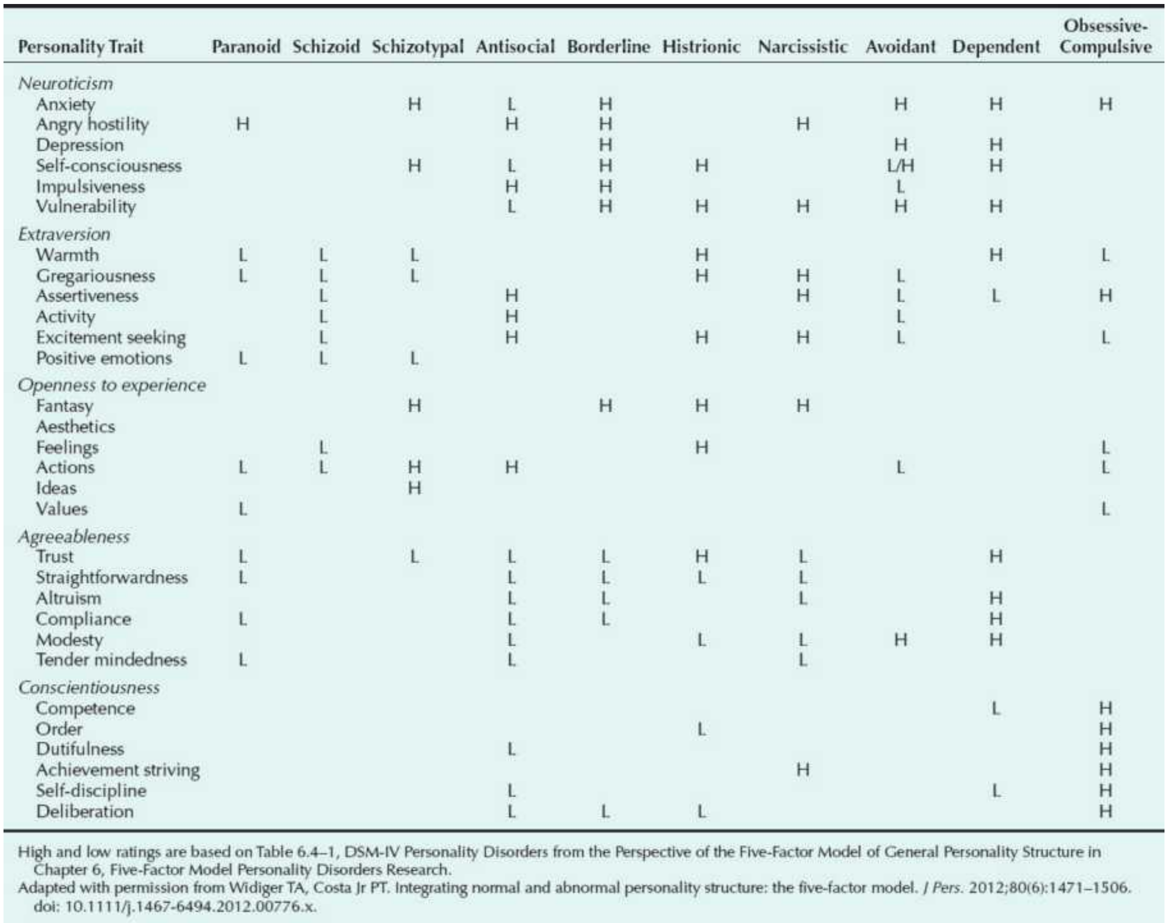
Revisions in the DSM-5. More than previous editions, the DSM-5 highlights the importance of individual differences, particularly in personality functioning and personality traits, stating that “the DSM like other medical disease classifications should accommodate ways to introduce dimensional approaches to mental disorders including dimensions that cut across current categories” (p. 5) but further “The DSM-5 Task Force recognized that it is premature scientifically to propose alternative definitions for most disorders.” (p. 13)

After a 12-year process (including research conferences, task force meetings, drafts, and revisions posted on a public website, etc.), the Personality and Personality Disorders Work Group presented an alternative dimensional model, which was strongly endorsed by the APA DSM-5 Task Force. This alternative model is similar to the dimensional FFM of general personality structure. “These five broad domains are maladaptive variants of the five domains of the extensively validated and replicated model known as the “Big Five” or “Five-Factor Model of Personality (FFM)” …” (p. 773).

However, the American Psychiatric Association Board of Trustees overruled the DSM-5 Task Force and retained all 10 DSM-IV-TR personality disorder categories, placing the Alternative Model in Section III—Emerging Measures and Models, hoping that such a move would allow additional research and give clinicians time to become better acclimated to this dimensional approach to diagnosis.

An alternative way to revise the diagnosis of personality disorders has also been offered by Thomas Widiger and colleagues, who have proposed a four-step process. In the first step, domains and facets of personality would be assessed, providing all the benefits of trait assessment described in the following discussion. In the second step, clinicians would identify specific problems in living associated with salient traits. For example, it might be noted that a patient high in self-consciousness experiences intense embarrassment when around strangers. In the third step, the clinician would evaluate the degree of impairment that the problems caused to determine if they are clinically significant. Does the patient’s embarrassment interfere with holding a job or finding a mate? Finally, in an optional fourth step, the clinician could interpret the full personality profile to see if it matched the prototype for an identified personality disorder. For example, if the patient was high in anxiety, depression, and vulnerability, as well as self-consciousness, and low in gregariousness, assertiveness, and excitement seeking, they could be considered to have an avoidant personality pattern (Table 6.4–2). A major advantage of this system is that patients who did not meet full criteria for any recognized personality disorder could still be treated for personality-related problems in living.

Table 6.4–2.
Hypothesized Relations between DSM-5 Personality Disorders and Five-Factor Model Personality Traits



Personality Trait	Paranoid	Schizoid	Schizotypal	Antisocial	Borderline	Histrionic	Narcissistic	Avoidant	Dependent	Obsessive-Compulsive
Neuroticism										
Anxiety			H	L	H			H	H	H
Angry hostility	H			H	H		H			
Depression					H			H	H	
Self-consciousness			H	L	H	H		L/H	H	
Impulsiveness				H	H			L		
Vulnerability				L	H	H	H	H	H	
Extraversion										
Warmth	L	L	L			H			H	L
Gregariousness	L	L	L			H	H	L		
Assertiveness		L		H			H	L	L	H
Activity		L		H				L		
Excitement seeking		L		H		H	H	L		L
Positive emotions	L	L	L							
Openness to experience										
Fantasy			H		H	H	H			
Aesthetics										
Feelings		L				H				L
Actions	L	L	H	H				L		L
Ideas			H							
Values	L									L
Agreeableness										
Trust	L		L	L	L	H	L		H	
Straightforwardness	L			L	L	L	L			
Altruism				L	L		L		H	
Compliance	L			L	L				H	
Modesty				L		L	L	H	H	
Tender mindedness	L			L			L			
Conscientiousness										
Competence									L	H
Order						L				H
Dutifulness				L						H
Achievement striving							H			H
Self-discipline				L					L	H
Deliberation				L	L	L				H

High and low ratings are based on Table 6.4–1, DSM-IV Personality Disorders from the Perspective of the Five-Factor Model of General Personality Structure in Chapter 6, Five-Factor Model Personality Disorders Research.

Adapted with permission from Widiger TA, Costa Jr PT. Integrating normal and abnormal personality structure: the five-factor model. *J Pers.* 2012;80(6):1471–1506. doi: 10.1111/j.1467-6494.2012.00776.x.

Application of Theory to Therapy

Psychodynamic, behavioral, and humanistic theories all specify the causal mechanisms by which psychopathology is created and maintained and thus imply points of intervention. If maladjustment is caused by rigidly internalized conditions of worth, then unconditional positive regard in the therapeutic setting may provide a cure; if the problem is a learned behavior, then altering reinforcements may extinguish it. Trait models do not emphasize causal or developmental explanations and thus may seem to have no implications for psychotherapy. In fact, they have many.

Recent evidence on the substantial heritability of most personality traits clearly indicates that Allport was right: Traits do have some underlying neuropsychic structure. Research on the psychophysiology of traits is a topic of growing interest and parallels the extensive work done on the neurophysiologic basis of many forms of psychopathology. In this broad sense, then, psychopharmacologic approaches to psychotherapy are, in principle, consistent with trait theories of personality: If personality traits and disorders reflect brain processes, drugs that affect the brain may offer useful instruments for psychotherapy. In practice, there is still much to learn. For example, individuals with dysthymia, who score high on measures of trait depression, often do not respond to antidepressant medication.

Personality Assessment. Historically, the chief role of trait psychology in psychotherapy has been in diagnosis and assessment. A number of self-report measures, such as the MMPI and the Millon Clinical Multiaxial Inventory, were designed specifically to measure psychopathology and include primarily items that tap psychiatric symptoms. They can be regarded as measuring psychopathologic traits and states (although they have often been used in college and volunteer samples as measures of personality per se). These instruments are chiefly of value as aids to psychodiagnosis. General personality questionnaires, including the 16PF, the Guilford-Zimmerman Temperament Survey, and the Edwards Personal Preference Schedule, have also been used for decades in clinical psychology and psychiatry as part of a complete psychological assessment. Several measures of the FFM have recently appeared, including the Big Five Inventory and the NEO Personality Inventory, and there has been considerable interest in the clinical application of the FFM. The primary advantage of this model is its comprehensiveness. By assessing traits from all five dimensions, the clinician can efficiently obtain a full portrait of the individual.

Some psychiatrists are concerned that personality scores obtained from acutely depressed patients are invalid. This concern is based on the empirical finding that scores, particularly on scales related to the five-factor trait N, change with remission and on the belief that personality traits cannot change. If the latter belief were true, it would be necessary to conclude that depression distorts self-reports of personality. However, as Figure 6.4–2 suggests, personality traits may change if their biologic basis is altered, and acute major depression has demonstrated effects on brain functioning. Controlled studies and clinical experience suggest that trait scores obtained from acutely depressed patients are indeed informative in most cases.

Personality psychologists and psychometricians have devoted years to the development of self-report inventories, and the usefulness of this approach to assessment is beyond doubt. Self-reports, however, are by no means infallible. Patients may not understand their own personalities or may deliberately misrepresent themselves. Concerns about defensiveness and socially desirable responses have led to the use of projective tests, the development of special validity scales to detect and correct distorted responses, and reliance on the clinical judgment of the psychiatrist. Each of these possible solutions introduces problems of its own, however, and most clinicians rely on multiple sources of information.

One source of information that has been underused in clinical settings is informant ratings. Research in the past decade has confirmed that ratings on standardized instruments by significant others—usually spouses or parents—can provide reliable and valid assessments of personality. These findings appear to hold for clinical, as well as volunteer, samples. Personality ratings may be particularly valuable when patients are incapacitated or are strongly motivated to present an overly favorable or unfavorable picture of themselves. A case example of the clinical interpretation of informant ratings is given below.

Uses of Trait Profiles. Traits are enduring and stable features of the patient's behavior and experience, so assessing a broad range of traits gives the clinician a sense of what the person is like, which can be useful for many purposes beyond the formulation of a diagnosis. A complete personality profile can point to the patient's strengths as well as weaknesses, can help predict the course of therapy, and can aid in the selection of an optimal mode of treatment.

Humanistic theories of personality stress human potentials for altruism, creativity, and commitment and argue that psychotherapy must use these assets. Trait theorists would qualify that stance: They believe that some people are altruistic, creative, or committed, but others are not. Assessing traits allows the clinician to identify and capitalize on the particular strengths that characterize each patient.

Standing on trait dimensions can also give clues to the probable course of therapy. Patients who are low on the five-factor trait A are distrustful and uncooperative, and it may prove difficult to form a therapeutic alliance with them; by contrast, patients who are extremely high on A may be excessively compliant and become dependent on the therapist. The five-factor trait C involves commitment and self-discipline. Patients high in C will probably adhere to treatment recommendations and work hard to solve their problems; those low in C are less persistent and dedicated, and the therapist may have to work to motivate them.

Finally, a few controlled studies and a good deal of clinical experience suggest that personality traits influence the effectiveness of various kinds of treatment interventions. Interpersonal therapies, in which patients are required to speak a great deal about themselves, appear to be most effective for extroverts; pharmacologic management may be superior for introverts. Similarly, individuals who are high in the five-factor trait O benefit from such techniques as guided imagery, whereas those who are low in O prefer biofeedback. Ideally, the choice of therapies should be guided not only by the nature of the disorder but also by the enduring characteristics of the patient.

An in-depth case study incorporating trait data with other assessment perspectives is provided in Jerry Wiggins's volume on Paradigms of Personality Assessment. Madeline G was a flamboyant Native American woman. She had overcome a history of early delinquency to become a lawyer who fought for the rights of her people. She had no children, and her common-law husband left her a year after her personality assessment. This led to a period of depression, and 3 years after her assessment, she still remained alone. She provided self-reports on the NEO-PI-R, and her husband rated her. They agreed that she was extraverted, open to experience, and very low in agreeableness but disagreed on neuroticism and conscientiousness. Figure 6.4–3 plots her husband's ratings of her.

This is a dramatic profile, with a number of extreme scores. From her husband's perspective, she is high in neuroticism, especially anger, hostility, and impulsiveness. Although he sees her as high in most facets of extraversion, he rates her as very low in warmth. Similarly, he describes her as being uniformly low in facets of agreeableness. He acknowledges that she is high in achievement striving but claims she is very low in dutifulness and deliberation.

The four-step process of personality disorder assessment predicts that she would be vulnerable to a specific set of problems in living. Her high angry hostility means that she is likely hypersensitive to criticism and prone to react with rage. Her low warmth suggests that she may have difficulty developing or sustaining personal, intimate relationships. Low agreeableness can lead to rudeness that alienates friends and trouble with the law (as seen in her adolescent delinquency). Because she is very low in self-discipline, she might be expected to have difficulty holding a job, but in fact, she is successful in her career. Although personality traits suggest the possibility of certain problems in living, the clinician must determine whether or not those problems are present in a particular case.

The clinician must also judge whether the problems are severe enough to warrant a diagnosis and treatment. Madeline G did not seek treatment, but both her depression and inability to develop new intimate relationships after her husband left her might have justified a psychiatric intervention.

Whether Madeline G met the criteria for the diagnosis of one of the ten DSM-5 personality disorders cannot be ascertained simply by looking at her personality profile. However, she shares personality traits with patients who have paranoid, schizotypal, antisocial, borderline, histrionic, and narcissistic personality disorders. Conversely, she is unlikely, according to her husband's description, to have schizoid, avoidant, or dependent personality disorders.

Madeline G's personality profile suggests that if she were in psychotherapy, she would find it difficult to form a therapeutic alliance (low agreeableness) and might have some problems making a sustained effort at the work of therapy (low conscientiousness). But she does have a number of strengths, including high assertiveness and achievement striving. Because she is quite open to experience, she would be willing to consider interpretations and suggestions for change made by her therapist.

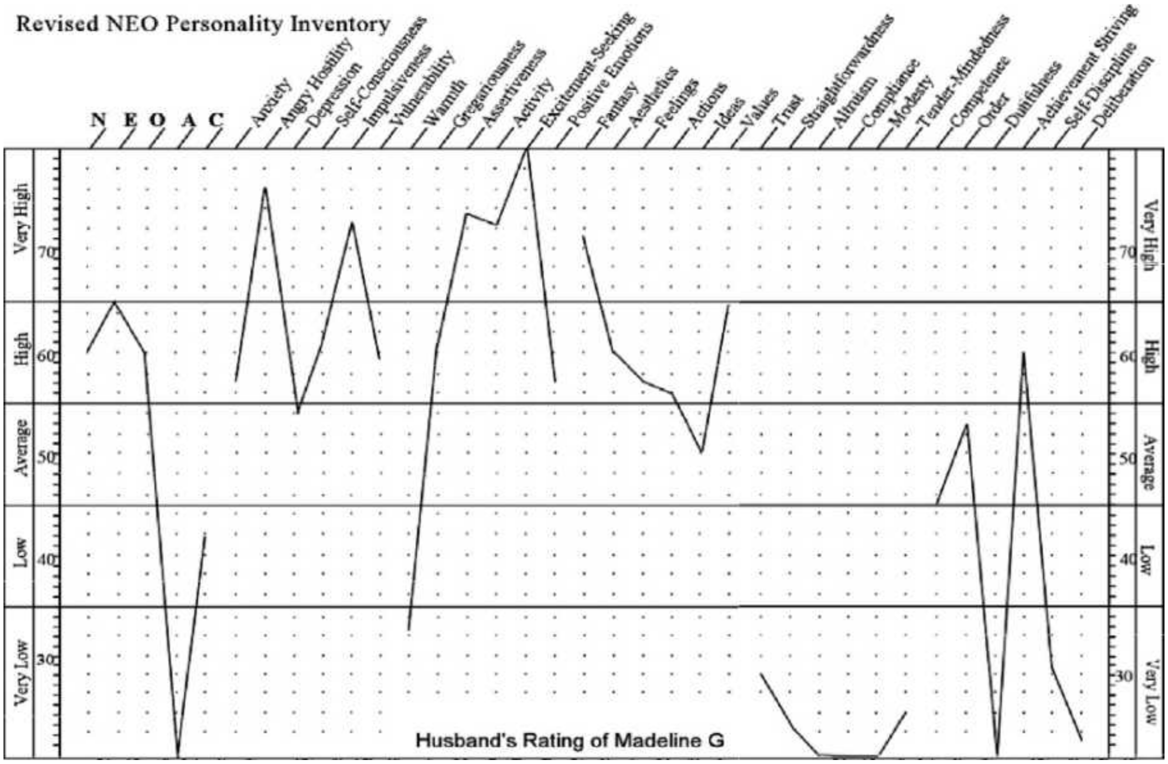


FIGURE 6.4–3. Personality profile of Madeline G as rated by her husband. T-scores (M = 50; SD = 10) comparing her to other adult men and women are plotted. The five factors are given on the left; the 30 facets, grouped by factor, are given toward the right. (NEO-PI-R profile form reproduced by special permission of the publisher, Psychological Assessment Resources, Inc., 16204 North Florida Avenue, Lutz, FL 33549, from the NEO Personality Inventory-Revised by Paul T. Costa, Jr., and Robert R. McCrae. Copyright 1978, 1985, 1989, 1991, 1992 by Psychological Assessment Resources, Inc. [PAR]. Further reproduction is prohibited without the permission of PAR.)

Clinical Applications for the FFM: Observer Ratings. The use of observer ratings is one area where research with the FFM can lead to further advances in clinical work and in identifying new domains. There are several values for using observer ratings of personality. There is no single method that is the gold standard for measuring an individual's personality. There is no one source or method for obtaining a true, unbiased profile of an individual. Rather there are multiple sources of information (e.g., self-report, observer rating, life outcome, etc.), and each provides its own, unique perspective on a person. Also, while each rating perspective has its own source of error across information domains, these errors are independent. Such uncorrelated error ensures that when scores converge across rating sources, one can be confident that the results are not contaminated by method biases. So, when both self-reports and observer ratings agree on the magnitude or level of the trait (e.g., low, average, or high), such convergence gives more confidence to the finding than either source alone. By using multiple sources of information, one is able to triangulate across them in a manner that removes any systematic method bias. When the different ratings do diverge, while providing an interpretive caution flag, such a situation may provide an opportunity for making a deeper evaluation of the client's motivational processes (see Piedmont, 1994; Piedmont, McCrae, Riemann, and Angleitner, 2000 in the references for discussions on observer-rated information).

One area where the use of multiple information sources can be diagnostically useful is with the assessment of couples. Many instruments designed to assess couple dynamics are very static in nature, in that they only evaluate each partner individually (e.g., a marital satisfaction scale) and/or address procedural aspects of the relationship (e.g., the roles expected of each other, such as who pays the bills, whose family is visited on what holidays, e.g., the ENRICH/PREPARE scales, Piedmont and Rodgerson, 2013). Yet, relationships are much more dynamic than what these types of scales capture. Interactions between members of couples are based on each member's own personality characteristics and the motivational goals they are pursuing. Levels of satisfaction are, in part, derived from each partner having a clear set of insights and expectations about their partners that enable them to accurately anticipate their partners' behaviors. Piedmont and Rodgerson have developed the "cross-over analysis" (COA) as a method for directly assessing these dynamic patterns. It involves a couple completing the NEO PI-3 for themselves and then rating the perceived personality of their partner.

This process generates four profiles, two self, and two observer profiles. Piedmont and Rodgerson outlined several different ways these data can be examined. The COA is the central interpretive strategy and requires that the observer rating of one member is compared to the self-report of the other. In this approach, levels of agreement between the two profiles speak directly to the types of issues the rater has with their partner. First, higher levels of agreement are associated with higher levels of relationship satisfaction in the observer; lower levels indicate less well-being with the partner. Second, scales where significant disagreements in scale scores exist (e.g., a difference of 15 or more T-score points) will indicate the types of difficulties the observer is having with the partner.

A couple who presented for marital counseling found the wife to have rated the husband significantly lower on O and C, while the husband rated his wife significantly lower on N and A. The wife found her husband to be emotively inadequate and very selfish. He did not like speaking about feelings, was not very supportive or caring, and seemed to want to be doing his own things. The husband, in turn, saw his wife as very emotionally stable and very antagonistic. In short, she was a real “bitch;” always yelling and criticizing him for being self-centered and unconcerned about her. He found these verbal attacks as an attempt to undercut his masculinity. What was missing in this relationship dynamic was that the husband did not realize how emotionally unstable his wife was. She was very insecure and anxious and needed much succorance and emotional support, something the husband did not recognize. Her yelling and berating of him was not an “attack” so much as an attempt by her to get her husband to respond supportively, to calm her fears, and reassure her. Her acting out was to get emotional help; he did not see the emotional need and rather interpreted these behaviors as an attack. As such, when she began her tirade, he would emotionally and physically withdraw to somewhere else. She saw this behavior as his inability to deal with and manage intimate emotions and to just “run away” from them. By examining the sources of these inaccurate perceptions and reframing the apparent underlying motivations, the couple came away with a different awareness of each other that promoted a more accurate understanding of their emotional needs.

The value of COA is that it provides a space for couples to examine their perceptions of each other in ways that are not judgmental or blameful. The comparison of the different protocols allows for an assessment of the views each partner holds of the other, and the resulting character styles that the rater believes are operating in their partner. Clinicians can then engage with these perceptions that are driving each person’s response style. Piedmont and Rodgerson provided a number of interpretive strategies for viewing discrepancies between the two sets of ratings. Comparing multiple profiles provides a rich amount of insightful information about couples.

Psychotherapy and Personality Change. If psychopathology is an expression or an outcome of personality traits and if, as longitudinal studies demonstrate, personality traits change little over time, how can psychotherapy be effective? The pessimistic answer is that it cannot. Many psychiatric disorders are lifelong or recurrent, and treatment consists of management rather than cure. It is well known that those who have the best prognosis for recovery are those who are initially least impaired. In these cases, the disorder may represent a transient adjustment reaction among individuals who have relatively healthy personality traits. Individuals high in N and low in A and C may seem to be poor candidates for psychotherapy.

However, such a pessimistic conclusion is unwarranted. Longitudinal studies show that people change little in the course of normal experience, but they do not rule out the possibility that direct interventions can make changes. It is unlikely that psychotherapy will make dramatic and lasting changes in basic personality traits, but more modest improvements may be enough to allow the patient to function adequately in daily life. Interventions may be particularly effective in early adulthood when traits are not yet fully developed. Even without changing personality, therapy may help individuals to adapt to their own nature. The chronically anxious person may learn techniques of relaxation; the disagreeable individual may learn social skills that improve interpersonal relationships.

In some sense, most forms of psychotherapy can be seen as learning experiences. Psychoanalysts promote insight into unconscious conflicts; behaviorists help their clients understand the contingencies that reinforce troubling behavior; humanistic psychologists encourage patients to discover their true potential. Trait psychology can also be a source of insight. All human beings are, in some respects, alike, and it is often comforting to learn that one is not alone in one’s suffering. In other respects, however, people are different from one another, and it can also be a therapeutic experience to learn this fact. Helping patients understand their own enduring dispositions can prepare them for some of the problems they face in life.

ACKNOWLEDGMENT

The authors would like to acknowledge the contribution of Robert R. McCrae to previous versions of this chapter.

Diagnosis and Psychiatry: Examination of the Psychiatric Patient

7.1 Psychiatric Interview, History, and Mental Status Examination of the Adult Patient

Rory P. Houghtalen, M.D., and John S. McIntyre, M.D.

George Engel wrote that the clinical interview in medicine is “Virtually indispensable for the physician–patient interaction, the well-constructed interview truly may be regarded as the most powerful, the most sensitive, and the most versatile instrument available to the physician.” Despite advances in science and technology, this statement remains true today, and perhaps nowhere in medicine is it more salient than in psychiatric practice, a specialty that relies almost entirely on a careful history and examination to develop a diagnosis.

Two primary aims shape the initial psychiatric interview. One is to develop a biopsychosocial database that informs diagnosis, risk assessment, and person (patient)-centered treatment planning. The other is to form a positive alliance that sets the stage for effective treatment that may follow the initial encounter. This chapter will focus on the initial psychiatric interview, but much of the commentary here is relevant to patient contacts in the course of treatment.

The settings in which psychiatric interviews occur include the psychiatric inpatient units, medical-surgical inpatient units, partial hospital programs, emergency rooms, outpatient offices, recovery services, nursing homes, other group homes, and correctional facilities. As the COVID-19 pandemic emerged and persisted, mental health professionals had to confront longstanding hesitancy to utilize distance technologies that have come to make virtual visits with patients a routine option in most mental health services in the United States and other developed countries. We address some specific issues related to virtual interviewing in the *Telepsychiatry* section of this chapter.

The sections of this chapter that follow will cover general principles and the processes of the diagnostic psychiatric interview from the initial request for consultation to the closing of the contact. Content includes commentary about documentation practices, addresses factors that influence the dynamics and quality of communication, and provides commentary on interviewing techniques. The chapter closes with a review of challenging patient scenarios and special topics related to the psychiatric interview.

GENERAL PRINCIPLES

Pre-Interview Contacts and Interactions

Referrals for psychiatric evaluation come from many sources, including patients seeking help, concerned family, other medical providers, schools, workplaces, and other agencies interested in the person's well-being. Some referrals are for reasons other than clinical treatment, for example, forensic evaluations, that require special considerations that this chapter's section *Forensic Interviews* briefly reviews.

The first contact in ambulatory settings usually begins with a phone call during which demographic, insurance information is obtained, and the patient (or other caller) is briefed on what to expect in the initial encounter, including the length of the encounter, fees, and other particulars of the office or service setting. Patients' first impressions influence attitudes and expectations. Typically, nonclinical staff are the first to make contact with new patients. Therefore, it is crucial to help them recognize and appreciate the anxieties that patients bring to a first encounter and offer strategies to help patients feel as much at ease as possible.

Clarifying the purpose of the referral with the referring source to tailor the evaluation is often essential, especially in a consult-liaison setting. Pre-encounter medical, mental health, and medication histories may be facilitated via mailed forms or secure electronic transmission. Patients may initiate retrieving relevant records prior to the first visit to enhance the database for diagnosis and treatment planning.

Many clinicians introduce self-report tools to gather history and identify symptom clusters and patterns. Sometimes, these tools are solicited before the first encounter or filled out before the first contact as part of the waiting room registration process to reduce the chances of missing a significant problem and make the initial interview more efficient. Broadband screening tools, like the Brief Patient Health Questionnaire, gather information about depressive and anxiety symptoms, social distress, traumatic exposure, and for female patients, screen for the possibility of pregnancy and other reproductive health issues. Disorder-based screening tools, like the Patient Health Questionnaire-9 (PHQ-9), aid in identifying patients likely to have a specific diagnosis, in this case, major depressive disorder. Others, such as the Quality-of-Life Enjoyment and Satisfaction Questionnaire (Q-LES-Q), are designed to survey social and emotional functioning. Patients are increasingly familiar with the use of such tools in medical settings. While this data-gathering method has many advantages, and research demonstrates that patients generally view these efforts as a sign of an organized, scientific method, the informed clinician knows that tools generate hypotheses but do not make a diagnosis. Any screening tool produces false-positive and false-negative identifications depending on its sensitivity and specificity and the base rate of symptoms in a population. The clinician who uses screening tools must be prepared to define the true significance of a screening result and balance tools with careful interview and examination.

Setting the Stage for the First Encounter

In contemporary behavioral health practice, the psychiatrist interacts with patients in diverse settings that may be variably suited to the psychiatric interview. With the advent of telemedicine, the clinician and patient may not even be in the same location. Nevertheless, certain principles for staging a successful first interview apply no matter the setting, including attention to optimizing comfort, safety, and privacy. Most patients come to their first encounter experiencing some level of trepidation. Some arrive cajoled or forced by others to have come at all. Anxieties are reduced by early clarification of the nature and purpose of the encounter and defining a mutual agenda before embarking on the interview. To the extent feasible, the patient should experience the clinician focused on them for their time together. To this end, unnecessary distractions such as beepers, text alerts, and phone calls should be minimized. Potential distractions related to note-taking and the electronic medical record are discussed in the *Special Topics* section of this chapter.

Comfort and Safety

For most patients, the emotional distress that brings a person to the initial interview is considerable and there is apprehension about what it means to see a mental health professional. Inadequate knowledge about mental health care and misconceptions about psychiatric treatment arising from stigma can fuel these anxieties. The skilled clinician is aware of these potential issues and interacts to decrease, or at least not increase the distress. An adage some attribute to Maya Angelou (others to Carl W. Buehner) offers some words of wisdom that apply to these first interactions with new patients: “I’ve learned that people will forget what you said, people will forget what you did, but people will never forget how you made them feel.” The patient’s first encounter experience is bound to affect engagement and set the tone for subsequent interviews or treatment that may follow and may affect attitudes about psychiatric and general medical care far into the future.

Not much is accomplished in any human interaction when the participants are physically uncomfortable or excessively anxious about personal and emotional safety in an environment. The clinician controls the environment in some settings, like a private office, but not so much in others, like a public clinic or the lock-up of a county jail. Regardless of where the initial contact occurs, interviewers should do what is within their power to adjust the environment to provide a reasonable level of comfort and assure the safety of both the patient and the clinician.

Engaging with patients known or found to have active psychosis, acute intoxication, or a history of aggression requires prudence and planning. It is wise not to interview patients with these problems in isolated areas. Optimally, areas used for interviewing should have adequate interpersonal space and arrangements that allow both patient and interviewer an easy exit without “going through” one another’s space. Tenuous situations may require modifications to usual interview techniques, including having another staff member present in the room during an encounter or standing by outside the door.

Explicitly discussing safety can reduce uncertainty, tension, and risk. The overtly disturbed patient is often calmed by acknowledging their discomfort and reassurance that the first goal is for the patient and staff to remain safe. Sometimes pointing out the clinician’s own anxieties about safety can level tension. A statement like this may help: “When you swear and speak in such a loud voice, it makes me anxious too. When I am very anxious, it is hard for me to pay attention to what you are saying, and interferes with my ability to help you. Do you think you can tone the language down a bit so that I listen better?” “Is there anything that I can do to help you feel calmer?” Even in a properly staged and managed interview, it may be necessary to shorten or quickly terminate the encounter if the patient escalates or becomes explicitly threatening. Judicious use of a therapeutic “show of force” can actually reduce the patient’s fears of loss of control by demonstrating adequate staff presence and a commitment to keeping everyone safe.

Privacy and Confidentiality

Privacy and confidentiality are essential components of therapeutic relationships. Staging the interview to ensure that others do not overhear the content is important. In some settings, such as a shared inpatient room or a cellblock in a jail, privacy may be difficult to establish. In less-than-optimal environments, judiciously steering the interview away from material that may overexpose the patient is wise.

The level of confidentiality afforded the patient varies depending on the nature of the encounter, making it essential to define the boundaries of confidentiality at the onset so that patients can make informed decisions about the nature and extent of material they are comfortable sharing. The clinician should consider reviewing with the patient situations that may lead one to share information without expressed consent. Examples include contacting informants to evaluate concerns about imminent suicide or violence risk, transferring information in medical or psychiatric emergencies, and mandated reporting of child abuse or neglect. Insurance claims and communications with pharmacies routinely require sharing of information. Minor children need to understand that a parent or guardian must be informed about diagnosis and treatment options to provide surrogate consent. Detailing the boundaries of confidentiality and exceptions in writing may strengthen trust and confidence in the clinical engagement.

Specific consent is first obtained (best in writing or at least carefully documented in the medical record) when information is shared outside of a genuine emergency or a mandated report. In the United States, the federal Health Insurance Portability and Accountability Act (HIPAA) rules define standards for the proper release of protected health information, and state-by-state regulations provide additional guidance for the management of protected health information. The details of this are beyond the scope of this chapter, but the clinician should understand and carefully follow the appropriate procedure for the release of information, understanding that HIPAA usually defers to the state regulation if it is more restrictive.

When it is necessary to share information without specific consent, the nature and extent of disclosure should be limited to that information essential to the task. This discretion conserves confidence to the extent possible, even when the clinician has a responsibility that may conflict with the patient's privacy.

Involvement of Third Parties

Often members of the patient's family, or other supports, attend a first encounter and may expect to be involved in the interview. These persons can be significant sources of collateral information, and ultimately everyone may agree they should be involved in treatment decisions and management. The patient and psychiatrist should discuss whether and how to involve significant others in clinical interviews and the nature and extent of information the patient wishes to share, assuming the patient is competent to assert confidentiality and an overriding factor, such as suicide or violence risk, does not trump the patient's choice. Patients typically appreciate the principle of "no meeting about me without me." Therefore, it is usually best to sequence the involvement of family or important others by first meeting privately with the patient and then, with the patient's agreement, bringing others into the encounter with the patient present.

Engagement and Relationship Building

The term "doctor–patient relationship" is a phrase used to describe that special interpersonal connection that sets the stage for healing interventions and on which current culture confers special status and obligations. Recently, the term "patient–doctor relationship" was coined, reversing the order of the parties to reinforce that the treatment should always be patient-centered. Projecting a friendly and open demeanor, maintaining a respectful and nonjudgmental posture, and demonstrating genuine interest in developing an empathic understanding of the patient's predicament are physician behaviors that build the type of rapport from which the patient–doctor relationship is forged. In the initial interview, the successful development of a trusting relationship allows the patient to feel comfortable enough to share sensitive and private information.

The relationship between patients and physicians will vary depending on their respective personalities and experiences. Equally important are the setting and purpose of the encounter. However, when followed, there are general principles that help ensure that the relationship established is one from which successful treatment can occur. Jerome Frank first examined therapeutic relationships from an anthropologic perspective in 1974. His observations discovered common characteristics that confer on an individual the status of healer regardless of culture. In Westernized cultures, specialized training and experience are factors. In addition to training and expertise, physicians are expected to behave in ways that project caring, instill hope, and maintain focus on the patient's best interest.

In the clinical setting, rapport can be defined as the harmonious responsiveness of the physician and patient to one another. It is vital that the patient experiences the evaluation as a joint effort and that the psychiatrist is genuinely interested in their story. Appreciating how and why the patient thinks and feels requires understanding the patient's life experience and perspectives in some detail and depth. Early in an initial interview, the clinician forms hypotheses about the patient's experience through what the patient says, what affects accompany the story, and, just as importantly, what is not said. As the interview progresses, the details of the patient's symptoms and story unfold, and patterns of thinking and behavior become evident, resulting in greater clarity about the patient's actual lived experience.

Empathy is the capacity to appreciate and understand the experience of the patient at an emotional level, achieved when the interviewer can imagine themselves in the patient's position while at the same time maintaining objectivity. Objectivity differentiates empathy from sympathy. Sympathetic identification with the patient may distort and stunt the development of a mature therapeutic relationship. Consider the experience of interviewing a patient with a borderline personality disorder. Sean Shea has noted, "One feels compelled to say a silent prayer for the poor patient with borderline features who meets a clinician who boldly proclaims, ‘I can feel your pain.’” An awareness and understanding of the dynamics of the patient–physician relationship is vital in helping the physician maintain objectivity while still transmitting concerned understanding and extending a helping hand. Empathic expressions (“*That must have been very difficult for you*” “*I’m beginning to understand how awful that felt.*”) serve to increase rapport. Frequently a nonverbal response (raised eyebrows or leaning toward the patient) or a very brief response (“Wow.”) will be similarly effective.

Ultimately, it must become apparent to the patient that the doctor understands and cares about his experience for effective treatment. In 1927, Francis Peabody wrote, “The secret of care of the patient is caring for the patient.” Caring for the patient is not automatic, and it is frankly difficult at times. James Groves (1978) published a classic paper entitled “Taking Care of the Hateful Patient.” Rael Strous and colleagues updated the paper for contemporary practice in 2006. Groves described patterns of patient behaviors that made them unlikeable to physicians and warned how this disdain could interfere with optimal medical care noting that if physicians become more aware of their feelings and reactions, they have increased opportunities to interact in a manner that can be helpful even under challenging situations.

The development of a healthy patient–physician relationship is reinforced when the physician is perceived as genuine. Being comfortable enough to laugh in response to a humorous comment, admit a mistake, or apologize for an error that inconvenienced the patient, like being late for or missing an appointment, strengthens the therapeutic alliance. It is also essential to be flexible in the interview and responsive to patient initiatives in relationship building. If the patient brings in an item, for example, a photo she wants to show the psychiatrist, it is good to look at it, ask questions, and thank the patient for sharing it. Much can be learned about the family history and underlying relationship dynamics from such a seemingly sidebar moment. The psychiatrist should be mindful that there are no irrelevant moments in the interview room.

At times patients will ask questions about the clinician that range from inquiries about training and experience to more personal matters such as marital status, sexual orientation, or religious beliefs. Depending on the reason for the interview, the nature of the question, and the particular characteristics of the setting and patient, these questions may properly be answered directly or reflected back to the patient to gain insight into the motive for the inquiry. Avoiding excessive sharing of personal information is a good general principle to adhere to, especially if the interview is likely to proceed into a psychotherapeutic treatment that relies on the relative anonymity of the therapist as a central tenet, such as in the case of psychodynamic therapy. On the other hand, the clinician should not be excessively stingy with information for more self-serving reasons than patient-centered at the risk of appearing aloof or callous.

A clinical example may help to illustrate these principles. An inpatient psychiatrist rounds for the first time on a newly admitted patient with major depressive disorder. The following conversation initiated their contact:

Psychiatrist: *Good morning, Mr. Smith. I'm Dr. Jones.*

Patient: (Interrupting) *Before you get started, I have one question for you. Are you Catholic?*

Psychiatrist: *Wow. That's quite a start. May I sit down?*

Patient: *You can sit down, but I'm not going to answer any questions until you tell me if you are Catholic.*

Psychiatrist: *I can see that's very important to you. Can you tell me why that is important?*

Patient: *I'm not going to say anything till you tell me.*

Psychiatrist: *I can tell you something about who I am and why I'm seeing you this morning.*

Patient: *Never mind about that stuff. I want to know if you're Catholic.*

The psychiatrist presses on, attempting to understand the reason for the question. Was there a prior unsatisfying experience with a

Catholic or non-Catholic psychiatrist? Does the patient worry that his religious concerns will not be understood or incorporated into care? The same resistant responses occur with each attempt to reflect on or address Mr. Smith's feelings.

Psychiatrist: *I'd answer the question, but I anticipate answering will lead to more questions about me, and we won't talk about you and why you were hospitalized or how you feel about being here.*
Patient: *No, that's the only question I have. If you answer that question, I'll answer whatever questions you have.*
Psychiatrist: *Okay. I'm Catholic.*
Patient: *Do you go to mass every week?*

There are occasions when, depending on the nature of the planned or ongoing treatment, it can be helpful for the psychiatrist to share some personal information even if the patient does not inquire directly. However, in all cases, the motive for self-revelation should be to strengthen the therapeutic alliance in the patient's service, not to meet the doctor's needs.

Meaning and Communication

An understanding of the process and content of the psychiatric interview would be incomplete without considering the role of the unconscious. From psychodynamic and neurobiologic perspectives, the reality is that most mental activity remains outside of conscious awareness. The psychiatrist and the patient both operate on conscious and unconscious levels and bring their respective personalities, personal histories, and idiosyncrasies to the encounter. The psychiatrist should remain alert for manifestations of unconscious processes in communication and relationship dynamics in themselves and the patient.

Unconscious processes in the patient–doctor relationship reveal themselves through transference and countertransference manifestations and various psychological defense mechanisms.

Transference is the process by which the patient unconsciously and often habitually displaces/transfers onto individuals in his current life those patterns of behavior and emotional reactions that originated with significant figures from earlier in life, often from childhood, like those attached to a parent or authority figure. Similarly, countertransference is the process whereby the physician unconsciously and reciprocally is involved in displacement to the patient. Remaining mindful that such distortions drive affects and behaviors of the patient and the psychiatrist alike reduces the burden of unnecessary emotional distress, unhelpful behaviors, and missed therapeutic opportunities when these processes are not recognized.

The primary care physician (PCP) offered considerable detail about an older woman’s background and symptoms in a letter sent to initiate a referral for psychiatric evaluation. Early in the psychiatrist’s first interview, it became apparent that the patient’s primary concern was the sexual relationship with her husband, which the psychiatrist found puzzling because the PCP was psychologically minded and had mentioned nothing about this in the letter. When asked if she had discussed this issue with her PCP, the patient responded, “Well, it took me awhile to even broach the topic with him because he is young enough to be my son. I tried to bring it up a couple of times, but he looked uncomfortable and changed the subject. I didn’t bring it up again; I didn’t want to bother him.” Subsequently, in a conversation about this patient, the PCP spontaneously commented, “She’s a very nice lady; she reminds me a lot of my mother.”

Other conscious and unconscious processes represented in the so-called “defense mechanisms” of psychodynamic theory shape and sometimes interfere with interviewing. The patient is generally unaware of the impact of these feelings and behaviors, which take many different forms, including tangential references to an issue, slips of the tongue, mannerisms of speech, avoidance of topics, exaggerated emotional responses, intellectualization, generalization, missed appointments, or other acting out behaviors; each of these may be examples of the unconscious at work. For example, phrases such as “to be honest with you” or “to speak frankly” suggest that the speaker is perhaps not being honest or speaking frankly. Interpreting the meaning of statements like these when they occur in initial interviews is tempting but generally ill-advised. It is better to note such manifestations while refraining from premature exploration of defenses until the relationship is secure enough to tolerate this manner of intervention and the patient seems ready to receive it as helpful, though a reflection such as “I would hope you will always be honest with me,” may be appropriate and constructive.

Open-Versus Closed-Ended Questions

An open-ended question identifies and introduces an area of inquiry but provides minimal structure about responding to the question or the desirable response. This style of questioning, in theory, allows the subject to respond spontaneously with as much detail as the subject chooses. It also minimizes the potential that the questioner will influence the answer. An example of an open-ended question is, “What can you tell me about this nervousness you mentioned earlier?” Closed-ended questions invite brief, “Yes” and “No” types of responses and may telegraph the desirable response. An example of a closed-ended question: “You are not nervous all the time, are you?”

The flow of a typical interview moves from open-ended questions that probe a particular topic to closed-ended questions that provide definition and detail when required. Both types of questioning are fruitful to explore topics fully, and each approach has its relative strengths and weaknesses. The balance of open- versus closed-ended questions will vary depending on the patient’s capacity to grasp the invitation of open-ended questions, the nature of the material explored, the patient’s response style (e.g., the patient prone to circumstantial responses may have to be structured more than others) the person’s openness to disclosure and the purpose and time available for the interview. No prescription defines the proper balance.

Person-Centered and Disorder-Based

The initial psychiatric interview has at least three crucial goals: establish a traditional biomedical diagnosis, understand the person's biopsychosocial dimensions, and build rapport. Clarifying the agendas of the clinician and the patient early in the encounter helps to define the boundaries of the interview and plan the best use of time. Starting an interview with a statement like this can help initiate agenda-setting: "We have all or part of an hour together today. My agenda is to understand the problems that bring you to this visit. I also want to learn the background of your life story to understand you as a person. Before we begin, I would like to know what you hope to get out of our meeting today and what questions you may have as we begin."

The individuality of the patient's experience is a central theme. The interviewer elicits the patient's life history in more or less detail subject to the constraints of time and the patient's willingness to share details of experiences and their private mental life. Adolf Meyer's "life-charts" were graphic representations of the material collected in this endeavor and were a core component of the "psychobiological" understanding of illness. The patient's early life experiences, cultural background, family dynamics, education, work history, religious beliefs and practices, hobbies, talents, relationships, traumatic events, and losses each, in concert with genetic and biologic factors, represent the field in which distress arose. An appreciation of the richness of life experiences and their impact on the person is necessary to develop a complex understanding of the patient. Gleaning all of this information in a first encounter may not be practical, but gathering enough to grasp the essence of both the problem and the person is an important goal.

Traditionally, medicine has focused on illness and deficits rather than strengths and assets. A person-centered approach focuses on strengths and assets as well as deficits. During the assessment, it can be helpful to ask the patient, "*Tell me about some of the things you do best.*" or, "*What do you consider your greatest asset?*" A more open-ended question such as, "*Tell me about yourself.*" may elicit information that focuses more on either strengths or deficits depending on several factors, including the patient's mood and self-image. Cultural norms also play an essential role in how much a person is willing to divulge about their inner experience and sense of self.

In addition to being person-centered, it is also vital that the psychiatric interview be disorder-based. Significant advances in medicine have occurred over the past two centuries as psychiatrists began to recognize that specific clusters of signs and symptoms were characteristic of disorders with common epidemiology, features, presentations, course, and response to treatment. Developing a criteria-based nomenclature, as cataloged in the *Diagnostic and Statistical Manual of Mental Disorders,* now in its fifth edition (DSM-5), has furthered psychiatric diagnosis and effective treatment. The DSM has some limitations, of course, but it transformed the esoteric methods of diagnosis that preceded it into a standardized method that improved the reliability of diagnosis and aided research and clinical work. In part, evidence-based psychiatric practice has flourished because of the increased reliability of diagnoses.

The best practice interview integrates the person-centered and the disorder-based approaches, and the interview process weaves back and forth between the two ending in a working diagnosis, differential diagnosis, and treatment plan. Incorporating the patient's needs and goals into the treatment plan is essential. Numerous studies have demonstrated that too often, the patient's goals for treatment (e.g., safe housing) are not the same as the psychiatrist's (e.g., decrease in hallucinations). This dichotomy may originate in an initial interview wherein the focus was not sufficiently person-centered but rather was exclusively or predominantly symptom-based. Even when the interviewer asks explicitly about the patient's goals and aspirations, a patient exposed on numerous occasions to what a medical professional is interested in hearing about may attempt to focus on "acceptable" or "expected" goals rather than expressing their version. Clinicians should explicitly encourage patients to assert their goals and aspirations and express them in their own words.

Time and Number of Sessions

The time devoted to the initial interview will vary considerably by the goal of the encounter and the setting. For example, about an hour is generally allotted in a typical outpatient treatment environment. However, in settings like emergency and hospital inpatient units where patients are often distressed, confused, actively psychotic, or agitated, the time may be foreshortened, and assessment may by default occur over multiple, brief encounters or rely heavily on collateral historians to obtain necessary information.

Table 7.1–1.
Sections of the Psychiatric History and Examination

- Identifying data
- Sources of information
- Chief complaint
- History of present illness (HPI)
- Past psychiatric history (including suicide and violence risk)
- Substance use/abuse/addictive behaviors
- Past medical history
- Family history
- Developmental and social history
- Review of systems
- Mental status examination (MSE)
- Physical assessment
- Formulation
- DSM-5 diagnosis
- Treatment plan

The clinician must accept that any history obtained is never complete or entirely accurate because of the nature of human memory and the distortions of perception that each person involved in an experience makes when recounting it, along with variations that occur with each retelling. In addition, an interview is dynamic, and some aspects of the evaluation are ongoing—new facts emerge so that the history often morphs to a lesser or greater degree depending on various factors, including the patient’s gradual comfort with revealing and the dynamics of the relationship between the patient and doctor.

HISTORY AND EXAMINATION

Process of the Interview

The key elements of the psychiatric interview are the patient’s histories and the mental status examination (MSE). The histories are based primarily on the patient’s subjective report but should be enriched by and compared to available records and the reports of collateral historians when indicated. In addition, it is essential to document the sources of information contributing to the evaluation with commentary on the quality and reliability of the sources. Table 7.1–1 lists the traditional elements of the psychiatric history and examination in the conventional sequence that findings are typically documented. The following sections will further define and discuss these elements.

The MSE is, in essence, the “physical examination” of psychiatry, a series of observations of signs and symptoms that are gathered and documented systematically. This chapter’s section, *Physical Assessment,* provides an overview of physical assessment in the context of psychiatric evaluation. The histories, MSE, and physical assessment define a working diagnosis.

Opening the Interview

After introductions (including clarifying how the patient prefers to be addressed), explaining the initial evaluation process, agenda-setting, and answering immediate questions and concerns, the interview itself begins.

The psychiatrist can begin with an open-ended inquiry, "*Why don't we start by you telling me your understanding of what has led to your being here today.*" Sometimes, the patient is uncertain why a referral to a psychiatrist was necessary or may feel frustrated or angered by the need to see a psychiatrist.

The following kind of conversation is not uncommon:

Mr. Smith: *Dr. Jones said I should see you.*

Doctor: *What's your understanding of why Dr. Jones recommended you see me?*

Mr. Smith: *Well, you're a psychiatrist, right?*

Doctor: *Yes, I am.*

Mr. Smith: *Well, after my tests all came back negative, he kind of implied this nervousness—that it's all in my head and I should see you. I think he's pretty frustrated with me*.

The patient should have an opportunity to express his feelings about the need for the encounter and his anxieties. The psychiatrist has an opportunity to inform the patient about their role as a medical specialist. They can also discuss the nature and importance of collaborative relationships, such as those with primary care providers or other mental health clinicians in patient care.

Chief Complaint

Traditionally, the chief complaint is recorded in the patient's own words, for example, "I have been depressed for months" or "I have a lot of anxiety in public speaking."

The following example illustrates the importance of recording the chief complaint as the patient offered it:

An older adult man presented in a psychiatric emergency room with the chief complaint, “I’m melting away like a snowball.” He had become increasingly depressed over the prior three months. Four weeks before this emergency visit, the PCP increased imipramine (an antidepressant) from 25 to 75 mg and added hydrochlorothiazide (a diuretic) 50 mg because of mild hypertension and slight pedal edema. Over the ensuing month, the patient’s condition deteriorated. In the emergency room, he was noted to have a depressed mood, a hopeless attitude, weakness, significant weight loss, psychomotor retardation, and was described as appearing “depleted.” He also appeared dehydrated. Blood work found elevated BUN and creatinine levels and hypokalemia. Examination of his medication supplies revealed that the medications were dispensed in the wrong bottles. The patient was actually taking 25 mg of imipramine, generally a nontherapeutic dose for depression, and 150 mg of hydrochlorothiazide, generally a supratherapeutic dose for diuresis. He was indeed “melting away like a snowball” from dehydration. Fluid and potassium replacement rapidly improved his general medical status and allowed the antidepressant to be safely titrated toward a therapeutic dose to treat his depression.

After establishing the chief complaint, the interview proceeds into the history of present illness (HPI).

History of Present Illness

The HPI is a chronologic description of the evolution of the symptoms of the current episode. As with any well-developed HPI in medicine, the psychiatric history includes details about the nature, frequency, severity, and pattern of symptoms, including exacerbating and alleviating factors. In addition, stressful life events, physical symptoms, medication changes, and substance use patterns may provide clues to the context of the presentation, the primary diagnosis, and comorbid conditions that can influence treatment choices.

The exploration begins, ideally, with an open-ended invitation like, “Please tell me how this problem began, what the experience has been like, and how it has played out over time.” The interviewer may have to structure the patient through parts of the story. It is crucial to try to answer the question, “Why is the patient presenting now?” (e.g., *“I’m here now because my girlfriend told me if I don’t get help with this nervousness, she will leave me.”*)

The psychiatrist reviews treatments the patient utilized during the current episode. They should attend to response, adherence, and attitudes about the treatment. The common use of alternative and over-the-counter treatments makes it crucial to inquire specifically about the use of these products.

Suicide and violence risk assessment (sometimes termed “lethality” assessment) is a standard element of the HPI and any complete psychiatric evaluation. Patients may not spontaneously announce dangerous ideation or acts for many reasons, including shame and fear that revealing may lead to undesirable consequences, including reporting and confinement. The *Suicide and Violence Risk History* section of this chapter provides additional information about risk assessment.

Rounding out a comprehensive HPI is a review of psychiatric and physical symptoms to detect additional symptoms and comorbid disorders relevant to comprehensive diagnosis, treatment planning, and prognosis. Two examples may illustrate the importance of a review of symptoms. First, failing to conduct a review of psychotic symptoms with the depressed patient could lead to a missed diagnosis of psychotic depression, the treatment of which varies significantly from nonpsychotic depression. Failing to conduct a medical review of symptoms, the clinician could easily miss that a patient with depression and congestive heart failure (CHF) developed shortness of breath after the PCP initiated a tricyclic antidepressant (TCA). Not recognizing that the TCA was exacerbating the CHF, the psychiatrist missed the opportunity to recommend a therapeutic alternative for depression that would steer away from inotropic side effects. Table 7.1–2 outlines major categories of psychiatric symptoms, including mood, anxiety, psychotic symptoms, that are part of a psychiatric review of systems. The *Review of Systems* section of this chapter and the figures that accompany it offer more information about the physical review of symptoms.

Past Psychiatric History

The past psychiatric history explores psychiatric illness prior to the current presentation, including symptoms, course, and treatment. Table 7.1–3 summarizes the items generally covered in a complete past history review. Details of past episodes, including the age of onset, context, nature and duration of episodes, the diagnosis offered, treatment applied and its setting, degree of response, treatment adherence, and attitudes toward treatment, are essential facts to gather. In addition, understanding the details of past treatments will lead to a better understanding of which treatments are viable alternatives and which to avoid.

Most psychiatric disorders have a recurrence pattern, and comorbidity is the rule rather than the exception. Some episodes of illness may have gone undiagnosed, especially milder forms of illness. Establishing the patient's best functional baseline and the extent of recovery between episodes provides a perspective on the impact of the problem(s) on the trajectory of the patient's life. It helps identify elements of a comprehensive treatment plan that optimizes the fullest possible recovery.

Fastidious review of prior medication trials provides valuable information to define reasonable treatment medication options and rule out others. Essential elements of this review include the dose and duration of trials, the nature and degree of effect and side effects, and whether the medication was used alone or in combination with other psychotropics or psychotherapies. Exploring adherence may lead to discovering obstacles such as negative attitudes, side effects, dosing complexities, stigma, social pressures, and financial burdens that affected prior medication trials. Normalizing problems with medication adherence helps to obtain frank responses. Consider these types of questions to invite the patient to acknowledge challenges with adherence: “Most people miss some doses of medication. How many times a week do you miss your medication doses?” “What gets in the way of taking the medication regularly?”

Table 7.1–2.
Psychiatric Review of Systems

Sleep

Sleep phase problems (initial, middle, terminal insomnia), total sleep time, abnormal sleep events

Mood

Depression: Persistent sadness, reduced interest or pleasure in usual activities, tearfulness, reduced or excessive sleep, reduced or increased appetite, weight loss or gain, low energy, reduced concentration, low libido, excessive or inappropriate guilt, psychomotor change (slowing or agitation), negative self-appraisal, helpless and hopeless thinking thoughts of death or suicide. A common mnemonic used to remember the symptoms of major depression is SIGECAPS (Sleep, Interest, Guilt, Energy, Concentration, Appetite, Psychomotor agitation or slowing, Suicidality).

Hypomania/Mania: Elevated, expansive, or irritable mood, decreased need for or inability to sleep, excessive energy, marked increase in goal and pleasure-directed activity, increase amount and pace of speech and thought, grandiosity, heightened libido, impulsivity and/or recklessness in behaviors such as spending and sex

Anxiety

Experience of panic attacks, somatic symptoms of anxiety, phobic, or social avoidance

Psychosis

Experience of hallucinations, delusions, disorganized behavior, speech or thought, negative symptoms

Obsessive-Compulsive

Repetitive intrusive and unwanted thoughts, compulsive behaviors to neutralize anxiety, hoarding behaviors

Trauma

Traumatic exposure; intrusive and avoidance symptoms, negative alterations in cognitions and mood, excessive arousal and reactivity

Behavioral

Substance use, gambling, impulse control problems, disordered eating, repetitive self-harm

---

It is similarly essential to gather details about psychotherapy trials, including the type of psychotherapy (individual, group, couple, or family), the model of psychotherapy (Was it evidence-based for the diagnosis?), and the frequency and duration of the treatment (Was it delivered in a manner that one expects to be effective?).

Table 7.1–3.
Past Psychiatric History

1. Details of prior mental health contacts
   - Sites/Levels of care: School-based, primary care-based, outpatient, emergency, inpatient, partial hospital, recovery programs
   - Nature of prior treatment: Psychotherapy, medications, technologies (e.g., ECT), recovery-based, alternative, and complimentary
   - Adherence and response to treatment
2. Prior acts of self-harm, suicide, aggression, and violence

To ensure the history is complete, the clinician should inquire about less common technologic modalities that the patient may have used, including light therapy, biofeedback, electroconvulsive therapy, and vagal nerve and transcranial magnetic stimulation.

Suicide and Violence Risk History

Developing the risk history is a critical component of a complete psychiatric history. The suicide and violence risk assessment field has matured to understand that risk is a dynamic process influenced by risk-enhancing and risk-reducing factors with origins in genetics, social learning, current environments, and the precise nature of present signs and symptoms. A complete discussion of risk assessment is beyond the scope of this chapter, but it is critical to point out key elements of a risk assessment history. These include details of past events of intentional self-harm and aggression, including the number of events, details of the context of prior dangerous behaviors, the level of intent and seriousness of behaviors, harmful outcomes, and the means used to harm self or others. A full exploration includes nonlethal behaviors that increase the risk of future lethality, including intentional self-injury. In addition to the behavior itself, the psychiatrist should explore the feelings and attitudes about the behavior and the emotional states that accompany or follow it. In addition, the psychiatrist should also try to understand to what degree the patient tried to conceal evidence of these behaviors. The degree of family or community support and religious beliefs that admonish against suicide are potential risk-reducing factors that should be assessed. Firearms account for slightly more than half of the suicide deaths in the United States, making screening for firearm access a routine aspect of psychiatric evaluation.

Additional information about risk assessment is found in other sections of this chapter: the *Mental Status Examination* section under *Risk Assessment,* the *Selected Challenging Interview Scenarios* under the headings *The Patient with Depression, The Potentially Suicidal Patient,* and *The Potentially Violent Patient*.

Substance Use, Abuse, and Addictive Behaviors

Substance use may be the primary reason for a referral and should be thoroughly evaluated. In addition, it is often a critical secondary problem. Substance use disorders can mimic or induce psychiatric syndromes, elevate the risk of suicide and violence, and impact safe medication prescribing. These facts highlight the importance of understanding the patient’s current and past patterns of substance use.

Starting the inquiry about substance use with a normalizing statement can help to reduce defensiveness and elicit a fuller history: “Most people drink alcohol at times, and many have also used a recreational drug at some point. I want to ask you some questions about your past and current use of alcohol and recreational drugs.”

Various tools can be used to aid in gathering the substance use history. Examples include the commonly used CAGE questionnaire, which has been modified to include other drugs (and now called CAGE-AID) though studies have found the operating characteristics of this tool wanting in primary care settings and with Caucasian females, pregnant women, college students, and less severe levels of drinking. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommends a procedure for alcohol use inquiry (available at https://www.niaaa.nih.gov/sites/default/files/publications/YouthGuidePocket.pdf) that offers the opportunity for education about safe levels of drinking for those patients at risk in addition to screening for current alcohol use problems using the alcohol use disorders identification test (AUDIT).

For each substance the patient acknowledges using, the interviewer gathers basic information about the age of onset, the pattern of use over time, current frequency, use level, and consequences (physical, mental, social, and legal). These facts help to identify problematic current or past patterns of use. Inquiry about tobacco use and problem gambling should be a part of the addictive behavior inventory.

The interviewer should identify periods of abstinence and determine what helped the patient achieve control of use, including any specialized treatment for substance use with details about the setting, nature of and response to treatment, and peer support engagement such as Alcoholics and Narcotics Anonymous.

Past Medical History

Past medical history is a bit of a misnomer, as this section of the initial interview and its documentation is usually used to review both past and present medical history. The interviewer is interested in obtaining an accounting of major medical disorders to develop a complete history and identify illnesses that could mimic a psychiatric disorder, contribute to the context of the presentation, or factor into treatment planning.

Medical disorders can precipitate a psychiatric disorder, such as an anxiety disorder in a patient newly diagnosed with cancer. They can also mimic a psychiatric disorder (e.g., hypothyroidism presenting “as if" major depression) or be precipitated by treatment of a psychiatric disorder (e.g., metabolic syndrome emerging during exposure to a second-generation antipsychotic medication). Medical disorders can also influence the choice of treatment of a psychiatric disorder (e.g., renal insufficiency and the use of lithium carbonate).

A well-developed past medical history archives current and past major medical disorders, surgeries, hospitalizations, and significant physical trauma, such as head injuries. Neurologic and endocrine disorders are of particular interest in psychiatry because of the significant overlap in symptoms and signs with psychiatric syndromes. For female patients, obtaining a reproductive and menstrual history is essential, as is a careful assessment of the potential for current pregnancy and plans for future pregnancy.

A thorough review of all current medications is essential because some medications used in other fields in medicine can create side effects that mimic psychiatric disorders and identify potential drug-drug interactions before prescribing. Patients have access to various over-the-counter, herbal, and alternative medications. They may not mention the use of these products unless specifically asked. Many over-the-counter and herbal/alternative products can produce psychiatric symptoms or interact with psychotropic medications in ways that range from nuisance side effects to outright hazards. Frank Ayd published results of the so-called "Brown Bag Study" that illustrated just how revealing an inspection of all the medications and products that a patient takes can be, and that serves as a reminder of the value of having the patient bring to the appointment their "brown bag" of bottles for inspection.

Allergies to medications must be identified, including the nature of the allergic response.

Family History

Because many psychiatric illnesses have a genetic predisposition, if not cause, a careful review of family history is essential to the assessment and can aid in diagnosis and establishing the expected prognosis. This area of history identifies family members with histories of known or suspected mental illness, substance use problems, and other behavioral problems, for example, criminality. Patients may not know the diagnosis of a family member but may be able to account for the relative's signs and symptoms from which reasonable hypotheses regarding diagnosis can be made. When the patient offers a diagnosis of a family member without much information to assess the reliability of the claim, the alleged diagnosis should be held skeptically or some attempt made to clarify it. Specific inquiry about family history of completed suicide is vital to suicide risk assessment because this finding elevates the index patient's future risk. In addition, a family history of medical disorders may offer clues to the patient's risk factors. For example, diabetes in first-degree relatives ought to raise a concern about the potential for metabolic syndrome with exposure to second-generation antipsychotics.

Developmental and Social History

Factors such as the reason for the interview and the amount of time available for it will determine how broad and deep the inquiries about developmental and social history can be, though it is crucial in first encounters for the clinician to give patients a sense that one is interested in their personhood and the contexts of their distress, not just their symptoms. Often in the first interview, an outline is obtained that is further developed in subsequent encounters. Table 7.1–4 outlines topics for developmental and social history.

The developmental and social history reviews the stages of the patient's life from gestation to the present to understand the essential exposures, relationships, and events that shaped the person's life story. One is interested in understanding the nature of the person's temperament and character and how the person has achieved developmentally appropriate role functions such as academic progress, work, peer and romantic relationships, and parenting capacity. Gestational and birth history, developmental milestones and early childhood development, the family of origin, cultural identifications, educational, occupational, legal, and military histories are explored. Histories of abuse (emotional, physical, and sexual), neglect (emotional and physical), and specific traumatic exposures are essential for a specific inquiry. The nature of the patient's current social environment is defined, including financial status, housing, and current relationships.

It is often helpful to review the social history chronologically; doing so provides a natural flow to the questions and ensures a complete history. Depending on the interviewer's assessment of the importance of missing information and assessing the credibility of the patient's account, it may be necessary to consult collateral historians to obtain a clear developmental and social history.

Table 7.1–4.
Social and Developmental History

1. Pregnancy and delivery
2. Developmental milestones
3. Educational (including history of special needs, in-school counseling, disciplinary problems)
4. Occupational history
5. Military
6. Legal
7. Relationships/committed relationships
8. Parenting
9. Leisure
10. Traumatic or potentially traumatic exposures (including neglect, physical and sexual abuse)

Review of Systems

As in a general medical interview, the review of systems is intended to capture any current physical signs and symptoms not already identified in the HPI or past medical history (including Table 7.1–2 and is organized by asking sentinel questions about the major systems of the body).

Mental Status Examination

The MSE is the functional equivalent of the physical examination in other areas of medicine. It is a systematic collection of the observations (e.g., signs such as blunt affect or rapid speech) and reported mental experiences (e.g., symptoms such as depressed mood or hallucinations) that produce a picture of the patient's current mental state. The interviewer makes these observations throughout an encounter and ultimately documents the findings together in the MSE section of the evaluation document.

Table 7.1–5 lists the traditional elements of the MSE along with examples of potential abnormal findings. The following sections offer commentary about each item of the MSE and model statements to illustrate how these findings might be documented in a medical record.

Appearance and Behavior

This section of the examination archives findings related to the patient's cooperativeness and behavioral activation levels, manner of relatedness, interaction, and state of grooming and dress.

> The patient appeared her stated age, was dressed eccentrically, and was poorly groomed. She seemed tense, distracted, and difficult to structure but was otherwise cooperative with the interview.

Table 7.1–5.
Elements of the Mental Status Examination with Examples of Abnormal Findings

Appearance and behavior: Odd or eccentric dress, poorly groomed, disheveled, unkempt, difficult to engage, evasive, indifferent, defensive, seductive, hostile

Eye contact: Avoidant, excessively prolonged, intense

Motor activity: Reduced activity, restlessness, agitation, posture and gait abnormalities, praxis problems, mannerisms and other stereotyped behaviors, posturing, tics, tremor, choreic, athetoid, and dyskinetic movements

Mood: Sad, irritable, angry depressed, elevated, expansive, euphoric, elated, dysphoric, anxious, incongruous with affect

Affect: Restricted, constricted, blunt, flat, labile, inappropriate to mood

Speech: Nonspontaneous, mute, rapid or slowed, low or high volume, abnormal pitch, tone or tempo, monotonous, robotic, stilted, excessive or reduced production, paraphasia, word approximations, poverty of content, dysarthria

Thought process/form: Derailment, tangential, circumstantial, flight of ideas, incoherence, blocking, perseveration, clanging

Thought content: Obsession, delusion, magical thinking, overvalued ideas, ideas of reference or influence, persecutory ideas

Perception: Hallucination, misperceptions (e.g., illusion), depersonalization, derealization, *jamais vu*, *déjà vu*

Risk assessment: Suicidal or violent ideation, intent, plan

Cognition: Impairments of orientation, attention, memory, language functions, calculation, visual-spatial capacity, following commands, impairment of intelligence, impairment of abstraction

Insight: Impairment along a continuum

Judgment: Impairment along a continuum

Eye Contact

Humans are keenly aware of eye contact and deduce a good deal about another's state of mind from it. Eye contact and its modulation in the psychiatric interview offer essential clues to the subject's internal emotional state. For example, a depressed patient may make little or no eye contact, an anxious patient's eye contact may be intermittent, whereas a patient with psychosis may stare and maintain intense eye contact. Eye contact is typically regulated to modulate the intensity and prevent inadvertent dominance displays. If a patient is especially intense or overtly paranoid, it is helpful to avoid prolonged eye contact.

> Eye contact was intermittent. When she made eye contact, it was inappropriately prolonged and intense.

Motor Activity

This examination section offers observations about the patient's general level of motor activity, posture, and gait and identifies the presence of abnormal movements such as tics, mannerisms, posturing, choreic, athetoid, and dyskinetic movements. If neurologic screening is conducted, such as testing muscle tone and deep tendon reflexes, these findings are archived here. In addition, many clinicians use this space to document the Abnormal Involuntary Movement Scale (AIMS) examination for tardive dyskinesia.

> Her gait was slowed and unsteady. When sitting, she was restless and rubbed the top of her head repetitively. On AIMS examination, she had mild rolling movements of her tongue at rest that were accentuated when her tongue was extended.

Mood

The terms mood and affect vary in their definition, such that one term often merges with the other. Several authors have recommended combining the two elements into the "emotional expression."

Traditionally, mood is defined as the patient's internal and sustained emotional state. Its experience is subjective, and hence it is best to use the patient's own words when describing mood. *Normal, calm, sad, happy, angry, irritable*, and *anxious* are examples of descriptors patients may offer.

> She said her mood was "calm."

Affect

Affect differs from mood in that it is the outward manifestation of a mood state visible to others. Mood is deduced to some extent from the person's emotional display. Some terms used to describe the quality (or tone) of a patient's affect include *dysphoric, happy, excited, euthymic, irritable, angry, tearful, blunt, and flat.* Speech provides affective information through volume, tone, and word choices. Quantity of affect is a measure of its intensity. For example, two patients both described as having depressed affect can greatly vary when one is mildly depressed and the other is severely depressed. Terms such as restricted, constricted, normal, or labile describe the affect range. Affect that correlates with the patient's stated mood and expressed thoughts is said to be appropriate or congruent to mood or thought content, whereas affect that contrasts sharply is said to be inappropriate with or incongruent to mood or thought content.

> Her affect was labile, ranging from inconsolable tearfulness to wild displays of irritability accompanying hostile speech, and was incongruent with her claim that her mood state was "calm."

Speech

Speech has an expected range of rate and volume and elements of pitch, tone, and tempo that are recognized within a normal range though cultural variation in these characteristics must be considered. It usually flows in a relatively linear manner conveying information efficiently. Strong emotions, such as intense anxiety, can lead to transient speech abnormalities. Certain psychiatric conditions, such as mania and schizophrenia, often have characteristic speech abnormalities that affect the linear flow of speech and its effectiveness in communication. The psychiatric interviewer should be alert for evidence of aphasic speech, which can be mistaken for disordered speech due to a psychiatric condition. Patients with speech disorders are often unaware that the communicative value of their speech is failing and may not show reciprocity in the speech that is characteristic of the interactive nature of spoken communication.

> At times, she was mute. When she did speak, her speech was excessive, difficult to interrupt, and came in rapid, loud bursts that made most of her communication ineffective.

Thought Process/Form

Thought process, also referred to as thought form, is how ideas are connected to convey thoughts to a listener or a reader in the case of written speech. Typically, ideas string together in a relatively linear pattern obeying conventions of grammar and syntax. Disordered thought takes many forms. Some descriptive terms include *circumstantial* (an inordinately circuitous route from question to answer), *tangential* (an answer to a question that veers off from the target of the question, but the connection may still be appreciated or inferred), and *derailment*, also called *loose associations* (thoughts proceed from idea to idea in a manner so oblique that the listener cannot follow the train of thought). Table 7.1–6 contains examples of named thought disorders and their typical characteristics.

Occasionally, her speech was linear and conveyed information well, but for the most part, she was quite disorganized with tangential and circumstantial speech. She was hard to interrupt during periods of flight of ideas and became frustrated when the interviewer tried to clarify what she was trying to say. At one point, she used an apparent neologism. For example, when asked how she was transported to the hospital, she said, “In a convestation, you fool”!

Table 7.1–6.
Examples of Disordered Thought Process/Form

Clanging: Use of the sounds of words rather than their meaning or conventional application to determine the connection between ideas

Circumstantial: Circuitous and overly detailed responses

Derailment (loose associations): Convoluted and random connections between ideas such that communicative value is lost

Flight of ideas: Derailment in the context of rapid speech

Incoherence (word salad): Complete disregard for conventions of word usage, grammar, and syntax resulting in incoherence

Neologism: A word created by the speaker with idiosyncratic meaning

Tangential: Responses that have only partial or remote connection to the original idea

Thought blocking: Loss of the goal of a communication and not being able to return to the topic

Thought Content

Thought content refers to the general themes of the patient’s ideation and is an area of the examination that identifies thought abnormalities such as obsessional thoughts and delusional ideation. The extent to which the examiner gains access to the patient’s private ideational life is determined by factors such as the patient’s comfort with the examiner and interviewing techniques to elicit this content.

Some patients share a broad range of content spontaneously and may even require structure to restrain the field of information they offer, while others perseverate or ruminate on specific thought content and require prodding to move beyond a narrow focus. Some patients guard content carefully. Guarding of thought content has many roots, including embarrassment or shame about the ideation, as is often the case with obsessional thoughts and paranoia that spills over into distrust of the interviewer.

A patient may reveal abnormal thought content freely, for example, complaining vigorously about persecution as a chief concern. At other times, gaining access to abnormal ideation is a delicate dance, especially when the patient is anxious about the consequences of revealing such material. Identification and exploration of delusional ideation often require particular care and respectful inquiry. A delusion is a false belief that the patient holds firmly despite evidence to the contrary and that is outside the normal range of beliefs of the patient’s culture or subculture. Common types of delusions are listed in Table 7.1–7. Delusions may be divided into two main groupings. One grouping distinguishes whether the idea is bizarre or not and the other whether the idea is mood-congruent or incongruent. Bizarre delusions are those that no one in the culture would consider a reasonable belief, whereas nonbizarre delusions are plausible but unlikely to be true. Mood-congruent delusions have themes consistent with the patient’s dominant mood state, for example, a depressed patient’s certainty that he has committed a mortal sin, whereas mood-incongruent delusions have no reference to a mood state, for example, the belief that aliens have implanted a device in one’s tooth through which thought is controlled.

A gentle exploration of the degree of conviction about a delusional belief can test the patient’s capacity to consider the possibility that their conviction is flawed. If one confronts the legitimacy of a delusional idea, this should only be done when there is a firm enough relationship for the patient to tolerate challenge and respect that delusions often serve an explanatory role. It may be hard for the patient to consider the possibility that the idea misrepresents reality, for doing so may require confronting an intolerable alternative truth.

Table 7.1–7.
Examples of Delusional Thought

Bizarre: A delusional belief that members of one's culture consider impossible

Erotomanic: Belief that another person is in love with one, usually someone perceived as having higher status

Grandiose: Belief that one has special powers, influence, or a special relationship with a deity or famous person

Identity: Belief that the identity of oneself or another person has been altered, replaced, replicated, for example, the Capgras syndrome.

Influence: Belief that someone of something outside one's self is influencing one to think, feel, or act in a certain way

Persecution: Belief that one is the subject of persecution, attack, harassment, or is being conspired against

Reference: Belief that an event, person, or object that is unconnected to the person has some special meaning or significance to the person

Somatic: Belief that a physical sensation or physical change is occurring to one's body caused by a source other than a normal biologic or pathophysiologic process

Thought broadcasting: Belief that the individual has thoughts that are produced by someone or something outside oneself

Thought insertion: Belief that the individual has thoughts that are produced by someone or something outside oneself

A delusion is a firmly held, false belief based on an incorrect inference that is unshakeable despite evidence to contradict it. It cannot be simply a cultural belief.

Consider the example of a young man with new onset of schizophrenia who is failing his college coursework. He attributes academic problems to a conspiracy among peers and faculties he is sure are modifying his work to ensure failure because his intellect threatens them. To consider the possible truth that there is something desperately wrong with his mind now interfering with his cognitive capacities and derailing his academic progress may be too much to bear.

When the psychiatrist inquired about his concerns about fellow students and his professors, he said, “Certainly you can see as well as I do that the other students and faculty members are threatened by me. They are colluding to undo me, to push me out of the way. No, I do not think this could be a trick of my mind, and the fact that you would even bring that up makes me wonder if you too are a part of this effort to ruin my academic career.” This appeared to be a delusion with persecutory and grandiose themes.

Perception

Perceptual abnormalities include phenomena like *hallucinations, illusions, depersonalization*, and *derealization*. Table 7.1–8 offers names and definitions for some of the more common types of perceptual disturbances.

Hallucinations are perceptions in the absence of external stimuli to account for them; they may occur in any of the five senses (auditory, visual, gustatory, olfactory, and tactile) and seem as authentic in the person’s experience as an accurate perception. Auditory hallucinations are the most common type of hallucination in nonorganic psychiatric conditions. In North American culture, the finding of nonauditory hallucinations should pique curiosity about an organic cause rather than a mental disorder. While visual hallucinations do present in North American culture (usually accompanying auditory hallucinations), some research in other cultures finds visual hallucinations to be the most common form of hallucinations in schizophrenia. The interviewer should be careful to distinguish between a true hallucination and a misperception of actual sensory stimulus (i.e., an illusion) and other phenomena, like hypnagogic and hypnopompic hallucinations, that are sleep–wake phenomena and a sign of a sleep disorder, not a psychotic illness. Most everyone can point to an example of a misperception or fleeting perception, for example, hearing one's voice called when no one else is home. These phenomena should not be mistaken for a hallucination, much less evidence of psychosis.

Table 7.1–8.
Examples of Perceptual Abnormalities

- Déjà vu: Perception that a present circumstance is the duplicate of an experience that has occurred in the past
- Derealization: Perception that one's surrounding and events are experienced as if the person is detached from them, or that they are distorted, changed, or unreal
- Depersonalization: Perception that one is standing outside oneself as a detached observer to surroundings, experiences, and events that occur
- Hallucination: The experience of a perception that seems genuine yet occurs without an actual external stimulus. The perception may occur in any of the five senses: auditory, gustatory, olfactory, tactile/somatosensory, or visual
- Illusion: Inaccurate perception or interpretation of an actual perception
- Jamais Vu: Perception that a present experience is entirely foreign when it actually should be very familiar

When documenting perceptual abnormalities, the interviewer should provide some description of the patient's experience, the context(s) in which the experience occurs, its frequency and intensity, the degree of the patient's conviction of the reality of the perception, and the degree of discomfort it causes, as well as any steps the patient may have taken to alleviate adverse effects of the experience.

In the case of auditory hallucinations, details of the nature and character of the voices can be critical to diagnosis: Does the patient hear one or several voices, simple statements, or complex sentences? Do the voices engage in a conversation or comment on the patient's thoughts? Generally speaking, the more complex the hallucinations, the more likely they are due to a schizophrenic spectrum condition. Whether the voices urge or command the patient to actions, including suicidal or violent behavior, is crucial to risk assessment.

As with delusions, the character of hallucinations is often divided into those that are mood-congruent (e.g., a depressed patient hearing a voice chiding her for failure and urging her to suicide) and mood incongruent (e.g., a patient with schizophrenia who, despite being quite paranoid hears female voices making warm, sexual comments that he finds arousing and soothing).

> The patient is experiencing hallucinations. She said, "Yes, I do hear a voice that keeps repeating statements like "you have failed as a mother, you will lose your family, you might as well be dead.""

Risk Assessment

Suicidal, violent, and homicidal ideation fall under the category of thought content, but many interviewers document these findings in a separate section of the examination labeled risk assessment. Risk assessment is an essential aspect of any initial clinical psychiatric evaluation.

Developing an in-depth understanding of high-risk ideation requires something more than simply asking the subject, "Are you suicidal or homicidal?" This approach will be an improper use of the closed-end question if one wants to know about this type of ideation. Ideas about suicide and violence are among the most private of thoughts. Patients are often hesitant to divulge ideation for fear of how the revelation will be received and the clinician's actions. Most will take any easy off-ramp to avoid it. A helpful approach begins with a normalizing statement followed by a question. For example, “In my experience, people who are struggling with the kinds of emotions and life problems you have described to me are also having ideas about death, dying, or taking their own life. Has this been the case for you?” A complete inquiry into risk addresses the presence of ideation and the level of intent, plans, and preparations that the patient has considered. Questioning about suicidal and violent ideation generally flows best by moving along the continuum from ideation to action.

Because many patients will withhold specific information about recent suicidal behaviors or suicidal ideation, Shawn Shea recommends a technique called the chronologic assessment of suicidal events (CASE) approach (access at https://suicideassessment.com/the-case-approach/). This technique uses a sequence of specific behavioral questions to determine how close the patient was to a lethal attempt. For example, if a patient had suicidal ideation involving a gun, the psychiatrist might ask, “Is there a gun in the home?” If the answer is “yes,” then the interviewer continues with a series of follow-up questions until a “no” response is obtained: “Have you taken out the gun?” “Did you load the gun?” “Did you point the gun at yourself?” “How long did you point the gun at yourself?” “What stopped you from completing the attempt?” Any developed planning for or practicing suicide or violence should be viewed as a high-risk finding requiring immediate attention. The American Psychiatric Association Practice Guideline for the Assessment and Treatment of Patients with Suicidal Behaviors is one source for more detailed information about best practices in suicide assessment. The recommended interview methods are analogous to the CASE approach just described, highlighting the importance of hallucinations and delusions in promoting suicidal acts.

Insight

Insight is a frontal lobe/executive function providing the capacity to appraise whether one’s thoughts, feelings, behaviors, perceptions, and planned actions are appropriate and realistic, and by the capacity to reflect on how one’s presentation may be perceived and interpreted by others. In everyday clinical practice, the degree of insight is typically rated on a continuum from absent to full; many patients have partial insight. Furthermore, the degree of insight does not track neatly with the severity of the illness. For example, a person with dementia may be painfully aware of cognitive decline, while a person with a mild anxiety disorder may have little or no insight into their overreactions to a fear stimulus. When recording the level of insight, describing examples is more helpful than merely saying “intact.”

> Her insight appeared to be partial. She had some sense that her behavior was being perceived as abnormal but could not consider the possibility that she is ill in some way that requires medical attention despite the evidence for overt psychosis.

Judgment

Judgment is another executive function mediated by the frontal lobe that represents the capacity of the individual to appraise a situation or problem, consider and decide among alternatives, plan and execute a course of action and modify the course of action when necessary based on new inputs. At times, judgment is impaired despite adequate insight. For example, a patient may recognize that he is confused about money management, including the funds in his checking account, but decides to make a large purchase without clarifying his account balance.

Tests of judgment that do not require real-world decision-making generally offer little value to an accurate judgment assessment. Take the example of a patient just arrested for dancing nude down the middle of a busy street while yelling at passing cars in the throes of a manic episode. The patient may answer a question about what to do if one found a stamped envelope on the sidewalk with a socially acceptable response such as, “mail it,” but the clinician would not, therefore, assess judgment as good. For this reason, it is helpful to distinguish between the abstract application of judgment and demonstrable judgment. Most examiners rate judgment on a continuum from very poor to good.

Her social judgment in the context of the interviewer was fair. For the most part, she behaved well in the examination, but she did become loud at one point and called me a “fool.” Recent events in the community, for example, her disrobing in public, demonstrate very poor judgment. She stopped her medication weeks ago and is now unwilling to consider any psychotropic medication.

Cognitive Assessment

During the interview, the clinician will develop a history and make observations that inform the cognitive assessment. Vocabulary level and abstract reasoning capacity are rough surrogates for intellectual capacity. The use of cognitive screening tests can be quite helpful in defining areas of strength or deficit that may not be obvious in a casual conversation without using more specific probes.

Domains of cognitive function essential to the initial assessment include the level of alertness, orientation, attention/concentration, visual-spatial function, memory (registration and recall), calculation, receptive and declarative language functions, fund of knowledge, capacity to abstract, and executive functions including insight and judgment.

The amount of detail required in assessing cognitive function will depend on the purpose of the examination and findings that raise a concern about the possibility of cognitive problems, like a history of learning challenges or an apparent decline from a previous level of cognitive function.

Two bedside tests commonly used to screen for cognitive function are the mini-mental state examination (MMSE) and the montreal cognitive assessment (MOCA). Each requires about 5 to 10 minutes to administer. They are also scored on a 30-point scale providing cutoffs between normal range and levels of impairment. The MOCA supplants the better-known MMSE in many settings because it tests a broader range of functional problems, identifies mild cognitive impairment, and provides administration instructions in many languages. The MOCA is available as an open-source product accessed at www.mocatest.org though it now requires users to complete online training to gain full access to the tool, while the authors of MMSE currently assert copyright protection. Because of these copyright issues, several other screening instruments have been developed, such as the informant questionnaire on cognitive decline in the elderly (IQCODE) and the Saint Louis University mental status exam.

Physical Assessment

The extent of physical assessment will depend on the nature of the referral, the setting, and the history and MSE findings. In the outpatient setting, routine physical examination is not generally a part of the initial consultation, while it is often critical to an emergency department or inpatient setting. Psychiatrists do not usually conduct comprehensive physical examinations but may conduct focused examinations such as neurologic or thyroid examinations. The psychiatrist generally relies on the PCP to conduct the physical examination in the outpatient setting. It is helpful in the initial evaluation to record the date of the most recent physical examination and review recent laboratories that are available. All psychiatrists should be prepared to measure vital signs and conduct other measurements, like waist circumference, indicated when psychotropic medications are used. A home blood pressure cuff is a valuable purchase for patients seen exclusively or predominantly virtually. The AIMS is an example of a screening physical examination conducted at baseline and serially during treatment with antipsychotic medication to monitor abnormal movements like tardive dyskinesia. An in-person visit is often required to conduct the complete exam.

Reviewing and interpreting laboratory results and ordering relevant laboratory tests or special studies, such as neuroimaging, is a critical aspect of many psychiatric evaluations. Psychiatrists lacking confidence in interpreting test results should consult with medical providers that can interpret them and offer opinions about the significance of results in the context of other findings.

Closing the Interview

Inexperienced interviewers are often naive to the importance of the last 5 to 10 minutes of the first encounter and find the closing of encounters challenging. It is helpful to alert the patient to the remaining time: "*We have to end in about 10 minutes.*" This signal allows the patient to plan how to use the time, particularly if they have delayed or failed to address something significant. Directly asking the patient if there is anything more they want to share before the end of the encounter is a valuable technique to reduce the patient's risk of bringing up an important issue "at the door" that cannot be adequately addressed. Sometimes late interview disclosures are too complex to address in the remaining time. If so, this may indicate a second interview to complete the evaluation. It is essential to leave time to share opinions and recommendations and answer questions about the diagnosis and plans.

COMMUNICATION OF OPINIONS AND RECOMMENDATIONS

The Formulation

The psychiatric interview and examination culminate with a case formulation that pulls together the biopsychosocial data into a working hypothesis about diagnosis and recommendations for treatment. The formulation should include a brief summary of the relevant findings from the history and examination, including the psychosocial contexts in which the problem has developed, and comments on the relevant contributions to the presentation of personality function, medical problems, social stress, and other social and cultural factors.

Although the formulation typically comes at the end of an evaluation document, the hypothesis-checking process is a dynamic one that continues from the first contact with the patient to the summary of opinions. Since most psychiatric diagnoses represent syndromes that often have overlapping features and presentations, a differential diagnosis of possibilities other than the working diagnosis is usually found in the formulation. It usually includes plans to obtain other data (history, tests, studies) to sharpen the diagnosis when this is indicated. The DSM-5 is the standard to establish a criteria-based diagnosis in the United States. Some other areas of the world use ICD-11. The two systems crosswalk in coding frameworks.

Finally, the formulation should include a summary of the risk assessment with estimates of acute and long-term risk of suicidal or violent behavior and an opinion about the appropriate level of care that will lead to a safe and successful outcome.

Treatment Recommendations

Consultations initiated by the patient and those requested by other professionals for input or care collaboration will usually include treatment recommendations. However, certain types of evaluations, for example, disability determination, competency assessment, and other forensics-related assessments, may not.

When evaluation produces treatment recommendations, these are typically shared with the patient after the encounter in a manner consistent with the patient’s capacity to receive and process the information and with explicit discussion of matters relevant to informed consent for recommended treatment. Treatment discussions typically involve much psychoeducation about diagnosis, the nature, risks, benefits of recommended treatments, and information addressing stigma and adherence. It is wise to involve significant others in these conversations, especially if there are concerns that the patient may need assistance in processing information and making decisions to ensure that decisions are consistent with the patient’s best interest. Recommendations may include referral to other professionals, or peer supports such as the National Alliance for Mental Illness (NAMI), the Mental Health Association (MHA), or Alcoholics Anonymous (AA). In addition, plans for crisis contacts and supports are typically addressed. These counseling and coordination of care efforts should be documented in the medical record.

TECHNIQUES

This section of the chapter will review several specific techniques that aid in facilitating and expanding information acquisition referred to here as “facilitating” and “expanding” interventions. Also reviewed here are some interventions that may prove to be counterproductive and interfere with patients telling their stories, which can interrupt the development of the therapeutic alliance.

Facilitating Interventions

Facilitating interventions enable the patient to continue sharing their story and help promote a positive patient–doctor relationship (Table 7.1–9). At times, some of these techniques may be combined in a single intervention.

Table 7.1–9.
Facilitating Interventions

Reinforcement
Reflection
Summarizing
Education
Reassurance
Encouragement
Acknowledging emotion
Humor
Nonverbal communication
Silence

Reinforcement. Brief phrases such as “I see,” “Go on,” “Yes,” “Tell me more,” “Hmm,” or “Uh-huh,” all convey the interviewer’s interest in the patient continuing. These phrases should fit naturally into the dialogue.

Patient: *For the past two months, I've been waking up at about 4 AM, and I can't get back to sleep. I feel anxious, like something bad is going to happen. A lot of times, I feel bad all day; it's only about 8 PM when I begin thinking of going to bed that I feel a little bit better.*
Psychiatrist: *I see.*
Patient: *I used to be a good sleeper. This seemed to come out of nowhere. It's a miserable feeling; I can tell you that.*

Although seemingly simplistic, reinforcement interventions are critical in encouraging the patient to continue sharing material. Without these reinforcements, the interview often becomes less productive.

Reflection. By using the patient's words, the psychiatrist indicates that they have heard what the patient is saying and conveys the implicit message that they are interested in hearing more.

Patient: *I don't know what's happening. I don't like going in to work anymore. The other guys at work are really starting to bug me.*
Psychiatrist: *Really starting to bug you.*

This response is not a question. A question with a slight inflection at the end calls for clarification (see below). The reflection is not stated with a challenging or disbelieving tone but rather as a statement of fact: the patient's experience is what it is, and the psychiatrist hears it. Sometimes it is helpful to paraphrase the patient's statement so it does not sound like it is coming from an automaton. However, in the example provided, the interviewer is unclear what the patient meant by "bug me," so changing the words (other than the pronoun) may steer the patient in a different direction.

Summarizing. Periodically during the interview, it is helpful to summarize what the patient offered about a specific topic. This approach provides the opportunity for the patient to clarify or modify the psychiatrist's understanding and possibly add new material.

Psychiatrist: *So, as I understand it, ever since you got a new boss this spring, things began to happen. You began to feel more anxious, and some of the comments of your coworkers really bothered you.*

Patient: *Yeah, and now that I think about it, around that time, my wife started complaining I wasn't fun anymore.*

New material has been introduced. The psychiatrist may decide to explore the previous discussion further and return to the issue concerning the patient's wife later.

Psychiatrist: *I want to hear about how things were between you and your wife, but before we talk about that, is there anything else you can say about how you felt at work?*

Education. At times in the interview, it is helpful for the psychiatrist to educate the patient about the interview process.

Patient: (after considerable hesitation) *There are some problems at home, but I don't know if that's what I'm supposed to be talking about.*

Psychiatrist: *It's helpful to talk about whatever has been bothering you. If I think we're getting off track, I'll let you know. Tell me about the problems at home.*

If this is not the first session and the patient has generally been sharing information, it might be helpful to focus on the hesitation.

Psychiatrist: *It seems difficult for you to mention that. Why do you hesitate to talk about the problems at home?*

This may lead to a discussion of confidentiality, loyalty to family members, or the nonjudgmental stance of the psychiatrist.

Reassurance. It is often appropriate and helpful to provide reassurance to the patient. For example, accurate information about the usual course of an illness can decrease anxiety, encourage the patient to continue to discuss their illness, and strengthen their resolve to continue in treatment.

Patient: *I don’t think I’ll ever feel better.*

Psychiatrist: *I understand how hopeless it feels for you right now. Feelings like that are common in depression, but most people with this type of depression do get better, and I think it’s very likely you will also.*

It is generally inappropriate to reassure the patient when the psychiatrist cannot predict with some confidence what the outcome will be. In these cases, the psychiatrist can assure the patient that they will continue to be available and help in whatever way they can.

Encouragement. It is difficult for many patients to come for a psychiatric evaluation. Often, they are uncertain about what will happen, and receiving encouragement can facilitate their engagement.

Patient: *I’m not doing very well describing this nervousness. I’ve never done this before.*

Psychiatrist: *I think you are doing well in describing the nervousness. As you talk, I’m getting a clearer picture of what it’s been like for you.*

The psychiatrist is careful not to overstate the progress in the interview. The patient is given positive feedback about their efforts, but the secondary message is that although the “picture” is getting “clearer,” more work is needed.

Acknowledgment of Emotion. The interviewer needs to acknowledge the expression of emotion by the patient. This acknowledgment frequently leads to the patient sharing more feelings and being relieved that they can do so. Sometimes a nonverbal action, such as moving a tissue box closer can suffice, or be used as an adjunct behavior to an empathic comment.

Patient: *He was a good friend.*
Psychiatrist: *As you talk about him, you look very sad.*

If the display of the emotion is clear (e.g., patient openly crying), then it is not helpful to comment directly on the expression of the emotion.

Patient: (sobbing) *I really miss him.*
Psychiatrist: *I see that you are crying.*
Patient: *You’re very observant.*

It is better to comment on the associated feelings.

Psychiatrist: *You feel awful without him.*

Humor. At times, patients make humorous comments or tell a joke. It can be beneficial if the psychiatrist smiles, laughs, or even, when appropriate, adds another punch line. This humor sharing can decrease tension and anxiety and reinforce the interviewer’s genuineness. It is vital to be sure that the patient’s comment was indeed meant to be humorous and that the psychiatrist conveys that she is laughing with the patient, not at the patient.

Silence. Careful use of silence can facilitate the progression of the interview. The patient may need time to think about what has been said. They also may need time to experience a feeling that has arisen in the interview. The psychiatrist who cannot bear the anxiety of silence may terminate it prematurely retarding the development of insight or the expression of feeling by the patient. As an experienced interviewer encouraged a new trainee, “Don’t just do something, sit there.”

On the other hand, extended or repeated silences can deaden an interview and lead to a struggle as to which party can outwait the other. If the patient is looking at their watch or looking about the room, then it might be helpful to comment, “It looks like there are other things on your mind.” If the patient has become silent and looks like they are thinking about the subject, then the psychiatrist might ask, “What thoughts or feelings do you have about that?”

Nonverbal Communication

Common facilitating interventions are often nonverbal. Nodding of the head, body posture including leaning toward the patient, body positioning becoming more open, moving the chair closer to the patient, putting down pen and folder, and facial expressions including arching of eyebrows all indicate that the psychiatrist is concerned, listening attentively, and engaged in the interview. Virtual interviewing interferes with some nonverbal techniques. Excessive repetition or exaggeration of nonverbal techniques risks being perceived as a caricature of the psychiatrist nodding their head repeatedly regardless of what is said.

Expanding Interventions

Several interventions can be used to expand the focus of the interview. These techniques (Table 7.1–10) are helpful when the line of discussion has been sufficiently mined, at least for the time being, and the interviewer wants to encourage the patient to talk about other issues. These interventions are most successful when the psychiatrist has established meaningful trust and the patient feels they are nonjudgmental.

Table 7.1–10.
Expanding Interventions

Clarifying
Associations
Leading
Probing
Transitions
Redirecting

Clarifying. Carefully clarifying what the patient has said can lead to unrecognized issues or psychopathology.

> A 62-year-old widow describing how it feels since her husband died 14 months ago repeatedly comments, “Everything is empty inside.” The resident interprets this to mean that her world feels empty without her spouse and makes this interpretation on a few occasions. The patient’s nonverbal cues suggest that she disagrees with this view. The supervisor asks the patient to clarify what she means by “empty inside.” After some avoidance, the patient states that she is indeed empty inside; all her organs are missing; they have “disappeared.”

The resident’s interpretation may have been psychodynamically accurate, but the interpretation interfered with the opportunity to discover a somatic delusion. Correctly identifying what the patient was saying led to exploring other thoughts and uncovered delusions. This vignette of “missing” the delusion exemplifies the interviewer “normalizing” what the patient is saying. The interviewer used secondary process thinking to understand the patient’s words, while the patient used primary process thinking.

Associations. As the patient describes symptoms, other areas that may accompany or relate to a symptom should be explored. For example, hearing about the patient's nausea leads to questions about appetite, bowel habits, weight loss, and eating habits. In addition, experiences that are temporally related may be investigated. For example, when a patient talks about their sleeping pattern, it can be a good opportunity to ask about dreams.

Leading. Often, encouraging the patient to continue their story can be facilitated by asking "what," "when," "where," or "who" questions. "Why" questions are generally not helpful early in an interview.

Patient: *And I said,* "*That's enough.*" (pause)
Psychiatrist: *What happened then?*

Sometimes the psychiatrist may suggest or ask about something not yet introduced by the patient because the psychiatrist surmises it may be relevant. In the courtroom, leading the witness is sure to raise an objection, but in clinical work, it can be helpful as long as the interviewer is not making too far an intuitive leap and is open to reframing the question pending a response by the patient.

Patient: "*…feels like my husband is always telling me what to do, criticizing my driving.*"
Psychiatrist: *You mentioned that earlier. Have there been other relationships where you have also experienced that?*
Patient: *Well…*(pause) *actually my father used to do that to my mother all the time. I really hated that.*

Probing. The interview may point toward an area of conflict, but the patient may minimize or deny any difficulties. Gently encouraging the patient to talk more about this issue may be quite productive.

Psychiatrist: *Tell me more about how things are at home.*
Patient: *Not really a whole lot to tell; everything is cool.*
Psychiatrist: *You mentioned that weekends are difficult.*
Patient: *I didn't mean that difficult.*
Psychiatrist: *OK. How are they different from before?*
Patient: *I don't know what you mean.* (pause) *Well, I guess it's a little different. Now my wife does her things, and I do mine.*

Transitions. Sometimes transitions occur very smoothly. For example, the patient is talking about their major in college, and the psychiatrist asks, "*Did that lead to your work after college?*" On other occasions, the transition means moving to a different interview area, and a bridge statement is helpful.

Psychiatrist: *That gives me a good idea about your nervousness. Perhaps now you can tell me about your health in general.*

Redirecting. A challenging technique for unseasoned interviewers is redirecting the focus of the patient. It can be tricky to move the interview in a different direction when reinforcing the patient telling their story. However, the reality of time constraints and obtaining a broad overview of the patient's life and the current problems make redirection necessary at times. Redirection is also used when the patient changes topics too quickly or persists in offering excessive information about a nonproductive or already well-covered area. For conscious and often unconscious reasons, the patient may avoid certain vital areas and need guidance in approaching these subjects.

Patient: (After beginning to describe some significant issues with her mother) *But enough of that, let me tell you about my job.*

Psychiatrist: *Before we move on to your job, perhaps you can say more about your struggles with your mother. It sounds like that has been very upsetting to you.*

Patient: (After much discussion about her arthritis) *And then six months ago, I saw a new rheumatologist…*

Psychiatrist: *I know your arthritic pains have been a big burden to you, and we can come back to that, but I would also like to hear more about the issues you mentioned with your daughter.*

Sometimes if the patient is wandering and does not respond to an attempt at transitioning, it is necessary to be more directive.

Psychiatrist: *I'm going to interrupt at this point because I am aware of the time we have left, and there are several other areas it would be good to talk about.*

Obstructive Interventions

While supportive and expanding techniques facilitate gathering information and developing a positive patient–doctor relationship, some other interventions are not helpful for either task (Table 7.1–11). Sometimes these interventions are technically correct, but if introduced in an unclear manner, unconnected to content, or poorly timed, they may be experienced as unresponsive to the patient's concerns or feelings.

Closed-Ended Questions. A series of closed-ended questions early in the interview can hinder the patient's story's natural flow and reinforce the patient providing one-word responses or brief answers with little or no elaboration.

Psychiatrist: *Did you have a happy childhood?*
Patient: (Pause) *Yes, I guess so.*
Psychiatrist: *Did you have friends?*
Patient: (Intuitively trying to get the interview pointed in a more productive direction) *Well, I guess it depends on what you mean by a friend.*
Psychiatrist: (Not joining the patient's attempt to enrich the discussion) *Kids you did things with. How many?*

This example illustrates that the patient can be a partner in the interview unless blocked by the psychiatrist.

Many patients, some of whom have previous experiences in therapy, come prepared to talk about even painful matters. Psychiatrists, particularly with supervision, learn from patients and refine their interviewing skills with time.

Compound Questions. Some questions are difficult for patients to respond to because more than one answer is being sought.

Psychiatrist: *How did you feel? What did you do?*
Patient: *I'm not sure what happened.*

Table 7.1–11.
Obstructive Interventions

Excessive use of closed-ended questions
Compound questions
Excessive “Why”? questions
Judgmental questions
Minimizing patient concerns
Premature advice
Premature interpretations
Abrupt transitions
Ambiguous nonverbal communication

Why Questions. Especially early in the psychiatric interview, “why” questions are often nonproductive. Often, seeking an answer to a “why” question is one of the reasons that the patient has sought help.

Patient: *I felt very depressed. I just couldn’t go on.*
Psychiatrist: *Why were you so depressed?*
Patient: *I don’t know. I thought you might know.*

Judgmental Questions or Statements. Judgmental interventions are generally nonproductive for the issue at hand and inhibit the patient from sharing even more private or sensitive material.

Patient: *I felt she wasn’t paying attention, so I yelled at her.*
Psychiatrist: *Don’t you know that yelling only makes matters worse?*

It would be better for the psychiatrist to help the patient reflect on that behavior’s success.

Psychiatrist: *How did that go?*
Patient: *Not good. Then she got upset about the yelling.*

Minimizing Patient's Concerns. In an attempt to reassure a patient, the psychiatrist makes the error of minimizing a concern.

Patient: *I worry I'm going to have a heart attack. My doctor says I have to lose weight.*
Psychiatrist: *I don't think you need to worry. You look pretty healthy, and your father is still alive.*

Rather than being reassured, the patient may feel that the psychiatrist does not understand what he is trying to express and trivializes the experience. Furthermore, the advice is counter to what the PCP has said and confused the patient. Exploring the concern is much more productive; there is likely much more material not yet shared.

Premature Advice. Early advice is often flawed because the interviewer does not yet know all the variables. In addition, it can preempt the patient from arriving at a plan for themselves.

Patient: *My boss is so demanding.*
Psychiatrist: *Why don't you get in early in the morning before he does and give him a list of what will improve everyone's performance?*

Premature Interpretation. A premature interpretation can be counterproductive even if it is accurate, as the patient may respond defensively and feel misunderstood.

Patient: *I was so angry at my neighbor when he said that, and I'm not sure why.*
Psychiatrist: *He reminds you of your brother and the way he was always trying to control you.*
Patient: (angrily) *He doesn't remind me of my brother; he doesn't even look like him.*

Transitions. Some transitions are too abrupt and may interrupt important issues the patient discusses.

Patient: *Ever since my father died, I've been feeling anxious.*
Psychiatrist: *Tell me more about your job.*

Nonverbal Communication. The psychiatrist repeatedly looking at their watch, turning away from the patient, yawning, or refreshing the computer screen convey boredom, disinterest, distraction, or annoyance. Just as reinforcing nonverbal communications can be powerful facilitators of a good interview, these obstructive actions can quickly obstruct an interview and undermine the patient–doctor relationship.

SELECTED CHALLENGING INTERVIEW SCENARIOS

Patients with Psychosis

Patients with psychotic symptoms are often frightened, guarded, and suspicious about the purpose of the interview and the intentions of the clinician. They may have difficulty with reasoning, thinking, or communicating. Hallucinations may cause inattention and distraction. The psychiatrist must adapt to match the capacity and tolerance of the patient. Patients with psychosis may not perceive their behaviors, speech, delusions, or hallucinations as abnormal in any way, making it essential to inquire in a manner that encourages the patient to share their ideational and perceptual experience without seeming judgmental of it.

Toward this end, prefacing direct questioning about psychotic symptoms by making normalizing statements such as “Many people have ideas that others find strange or different,” can increase the patient’s comfort with sharing delusional ideation and similarly for hallucinations by stating that, “Many people have had the experience of hearing a voice or seeing a vision.” Such a statement may help the patient talk more openly.

The psychiatrist should be alert for cues that psychotic processes may be part of the patient’s productions during the interview. It is usually best to ask directly about any such behaviors or comments.

During an initial interview, a 28-year-old man suddenly stood up and turned 360 degrees, sat down, and after a brief pause, resumed talking. When asked, “What just happened?” the patient responded that he “had to unwind.” While exploring this example of concrete, primary process thinking, several other psychotic features were uncovered.

By definition, patients with delusions have fixed false beliefs. With delusions, as with hallucinations, it is crucial to try to explore the symptoms in some detail. Patients are often reluctant to discuss their experience because of past occurrences of being dismissed, ridiculed, or confined when they revealed their thoughts and perceptions. They may ask directly if the clinician believes the delusion. Interviewers are advised not to endorse the false beliefs, but it is rarely helpful to challenge the delusion directly, particularly in the initial examination. It can be helpful to shift the focus of attention back to the patient’s beliefs while acknowledging the need for more information by responding like this: “I believe that what you are experiencing is frightening and I would like to know more about your experiences so I can form an opinion.”

With patients evidencing a high degree of suspiciousness, it is helpful to maintain distance and modulate statements or behaviors that patients may interpret as promoting excessive closeness, such as excessive use of empathic statements or prolonged eye contact. Harry Stack Sullivan recommended that rather than sitting face to face with the paranoid patient, the psychiatrist might sit more side by side (but not too near), “looking out” with the patient. While interviewing the psychotic patient, the interviewer should consider that the patient might be incorporating the clinician into the psychotic process. It can be helpful to ask about this directly, for example, “Are you concerned that I am involved?”

Acute psychosis raises concerns about the potential for violent behaviors that are further reviewed in this section under the heading *The Potentially Violent Patient*.

The Patient with Depression

The depressed patient may have particular difficulty participating in the interview due to psychomotor slowing, cognitive deficits, and lack of motivation to engage owing to the depression. In addition, feelings of hopelessness may contribute to a lack of engagement.

> Patient: “*What’s the use (of talking)? It’s not going to make any difference. Nothing is going to change.*”
>
> Psychiatrist: “*I’m glad that you can share that. It sounds like you feel hopeless about getting better. Hopeless feelings are common in patients who have depression. I think your condition will improve, and you will feel more hopeful.*”

The depressed patient’s responses to questions are often latent and may lack spontaneous elaboration. Depending on the severity of symptoms, the interviewer may need to turn to more direct questioning and abandon an open-ended format. The interview of severely depressed patients can be a laborious process and may require more time than expected to gather even minimally necessary information. Even then, collateral historians may need to fill in gaps in the patient’s history.

The Potentially Suicidal Patient

There are times in initial interviews when it is apparent that one is encountering a patient on the brink of suicide, but in many other instances, patients have suicidal ideation without betraying much, if anything, in the way of clues. For this reason, it is vital to conduct a suicide risk assessment in an initial psychiatric interview. Specific diagnoses and problems heighten suicide risk: major depression, borderline personality disorder, high anxiety levels, acute psychosis, acute intoxication, patients who have become hopeless about their substance use problems, acute grief and loss reactions, and patients with grave or burdensome medical problems. In addition, persons recently arrested and patients who are homicidal may also be suicidal. As discussed in earlier sections of this chapter, normalizing the potential for suicidal ideation is a good way to encourage patients to share their thoughts and feelings. An invitation like this can help to initiate the conversation about suicide: “Many people who describe a life event or the feelings that you have today are also having thoughts about death, dying, or even ending their own life. Has this been the case for you?”

The science of suicide risk assessment is beyond the scope of this chapter, but there are important risk factors that elevate suicide risk to survey as the history is developed. Some relate to demographics (e.g., age, gender, living alone, race and ethnicity, sexual orientation), others to certain factors related to diagnosis and clinical features (see above), and life experiences such as childhood physical and sexual abuse. Family history of suicide, prior attempts at suicide, and acts of deliberate self-harm are important historical risk factors. In addition, active substance use, acute psychosis, high anxiety levels, or insomnia seem to fuel suicide risk. Protective factors include the level of social support, children in the home, pregnancy, and religious beliefs that admonish suicide but are in themselves not entirely reliable guardrails.

The Potentially Violent Patient

Safety for the patient, interviewer, and others present is the primary concern when engaging with hostile or agitated patients. If one knows in advance that an encounter with a hostile or agitated patient will occur, there is an opportunity to plan and marshal supports. As noted elsewhere in the chapter, thoughtful attention to managing personal space and having an attendant during the encounter can reduce risks in these situations. In addition, it is good practice to alert other clinical staff in the area and security if an officer is present.

Reducing excessive stimulation of already hostile or agitated patients is a priority. Interviewers should be aware of their body position and avoid postures, behaviors, eye contact, tone of voice, and choice of words that could be perceived as threatening. Approach the interview in a calm, direct manner and take care not to make bargains or promises to elicit cooperation in the interview, for example, implying that cooperation will avoid an admission. These tactics will only likely escalate agitation and the potential for aggression when the patient discovers the examiner cannot deliver.

Managing the interview requires thoughtful choices about areas to explore and those to leave alone and the phrasing and timing of questions to avoid stirring up unnecessary conflict. Taking breaks, agreeing to leave a topic that causes tension for another time, and attending to basic comforts like hunger and nicotine replacement before pressing on with the interview may reduce tension and build rapport. Avoid unnecessary displays of dominance and give patients choices where there are reasonable options to maintain some semblance of control.

Despite best efforts, some interviews must be terminated when the patient’s agitation escalates. Generally, preceding unpremeditated violence is a period of gradually escalating psychomotor agitation such as pacing, loud speech, and threatening comments. As noted earlier in the chapter, some agitated patients will be calm when the interviewer shares that the patient’s behavior makes the interviewer too anxious to be helpful. However, there is no virtue in pressing on and taking unnecessary risks, especially when the interviewer is frightened. Instead, consider terminating the interview and seeking assistance if the patient’s behaviors escalate and do not readily respond to structure and feedback.

The hostile or agitated patient may be placing others in his community at risk. The most common victims of violence by acutely ill psychiatric patients are those who live or work close to the patient, such as family, residential staff, and coworkers. If the patient can tolerate it, explore feelings and attitudes about those close to him to discover persons who may be at particular risk. If the patient makes specific threats or identifies specific targets, take the threat seriously and carefully define the actual risk.

Like the assessment of suicide risk, a complete discussion of the violence risk assessment is beyond the scope of this chapter. Specific facts are worth noting here. First, research reveals more about risk factors for violence than protective factors. Among the critical risk factors are patient age (youth), lower intelligence, past acts of violence and general suspiciousness, and active psychosis; individuals physically or sexually abused as children are also at greater risk of violence. Interviewing for violence risk follows much the same pattern as that used for suicide risk assessment. The interview generally moves along the continuum of ideation to plan to action exploring the nature and extent of the patient’s ideation, planning, and intent. Like suicide assessment, the clinician seeks to define past instances of violence. This includes assessing the particulars of these episodes and the outcomes to understand the risk level during the interview and identify patients at elevated risk over time.

The Patient Engaging in Deception

For this discussion, deception is defined as the intentional production or exaggeration of symptoms. Psychiatrists train to maintain vigilance for deception while eliciting information, but they are not immune to being deceived. Studies show that even experienced clinicians will fail to recognize malingered mental illness in some settings. Patients engage in deceit for many different reasons. Some are motivated by secondary gains, like work excuses, disability, or to secure desired medications. Others seek primary gains, like the psychologic benefits of assuming a sick role.

A soldier in basic training presents to the military base mental health service with a long list of symptoms. He escalates the drama of his responses each time he perceives that the psychiatrist is not reacting to his productions as he expected. Finally, after describing some elaborate visual hallucinations that do not comport to those typically experienced by psychotic patients and that also failed to impress the psychiatrist, the soldier blurts out, “What’s the matter? You never heard of paranoid schizophrenia?” Later, the psychiatrist learned the soldier visited the base library to read about psychiatric illnesses and schizophrenia. The soldier admitted he was feigning symptoms to avoid an undesirable deployment.

There are no infallible means to detect deceit. However, there are markers in interviews that raise suspicion, including vague and contradictory responses, symptom claims that are inconsistent with functional findings, claims that are far beyond the variations of psychopathology seen in certain conditions or problems, or that are frankly preposterous. View skeptically patients that draw excessive attention to symptoms and those that become irritated with attempts to clarify the nature of complaints. This said, it is essential to remain cognizant that there are unusual presentations, and one should not assume that all that confuses or does not fit typical patterns is, therefore, evidence of deceit. Collateral historians become critically important when there is concern about the credibility of patient reports. Specific psychological tests are designed to detect deceit (e.g., the Word Memory Test), and others have validity scales imbedded in their structure that measure the nature of response style to identify likely exaggeration or suppression of symptoms in reporting (e.g., the Minnesota Multiphasic Personality Inventory [MMPI]).

It is critical to be confident in one’s opinion about deceit before confronting a patient with this conclusion. It is also essential to maintain an empathic approach when discussing findings, ideally helping the patient save face while accepting responsibility.

The following is an example of an exchange with a potentially malingering patient.

> "Would you agree that it is important for you to be truthful with me about your history and symptoms and for me to be truthful with you about my findings and recommendations? Okay, then, to be a good doctor to you, I must share that I believe that you are exaggerating some of the symptoms you have described. These are the reasons why I believe this to be so (clinician explains the reasons). I am concerned that you are trying to present yourself as ill in certain ways that, in the end, could lead to bad outcomes, like applying treatments that could do more harm than good. If I am right about this, let us start over and talk about what is really going on and why you might have tried to present yourself as ill in this way. Then I can see if there are ways I can help you with your predicament that are reasonable and safe."

SPECIAL TOPICS

Note Taking and the Electronic Medical Record

Many psychiatric interviewers take handwritten notes during the interview. With the advent of electronic medical records, some advocate for a method called "contemporaneous documentation." This method involves pausing periodically during the encounter or at the end to create all or part of the consultation document with the patient's participation. Advocates of this method point out that a patient increasingly has direct access to all or parts of their medical record through patient portals. Writing the note with the patient, so to speak, reduces the chances of documenting inaccurate information or writing statements in a manner that the patient might find offensive.

This is an example of how contemporaneous documentation might proceed:

Psychiatrist: “Now you have told me a lot about your current problem, and I’d like to pause now and document what you said to summarize it in the record. I will summarize what I am writing while I type it. You listen and tell me whether I have heard you correctly.”

The process of contemporaneous documentation can result in synergistic efficiency that allows summarizing, clarifying, and correcting information while completing documentation. For those that now offer an hour for the consultation and then do documentation after the encounter, extending the consultation to include time for contemporaneous documentation may improve time economy.

Note-taking and contemporaneous documentation in an electronic record during the interview presents some risks. These activities can interfere with observing nonverbal information, like affects and body language, that are often as or more important than what the patient says. Failing to recognize these nonverbal cues can result in losses of essential data and empathic failures affecting the development of rapport. The activities can also distract the patient and the interviewer if they dominate the interview.

Cultural Variation

One definition of culture is a common heritage, beliefs, and values that set expectations for behaviors, thoughts, and even feelings. Culture influences the patient’s attribution of illness, decisions about when and where to seek help, how distress is articulated or demonstrated to others (including when speaking with medical providers), and perceptions of necessary and acceptable forms of treatment. Often, individuals from a minority population are reluctant to seek help from a physician from the majority group, especially for emotional difficulties.

Just as the array of cultural syndromes and variations is beyond the scope of this chapter, interviewers cannot be aware of all culturally bound syndromes or idioms of distress. However, they should make an effort to learn about variant presentations and syndromes that affect cultural groups commonly encountered in the scope of their practice settings. Reducing the risk of overdiagnosis (e.g., misreading a cultural belief for a delusion) and the possibility of over or undertreatment resulting from inaccurate diagnosis are important reasons cultural awareness is essential.

By remaining humble and curious about the patient's cultural identifications and beliefs and being open and respectful, the psychiatrist increases the likelihood of developing a trusting working relationship and a collaborative and effective plan.

Interviewing with an Interpreter

Translated interviews require forethought and preparation. A professional translator is favored over using a person familiar to the patient whenever possible. Professional translators have training and experience to interact with patients and providers skillfully, the vocabulary skills to translate medical words and concepts, operate under a code of ethics that highlights confidentiality, and understand the importance of verbatim translation and neutrality. The use of nonprofessional interpreters risks a poor-quality translation fraught with all the challenges of agency, skill, and interpersonal dynamics that friends and family bring to the process of interpretation and too often lead to incomplete or frankly inaccurate communication.

It is helpful to speak with the interpreter before the interview to clarify the examination goals and expectations. Most professional interpreters are attuned to the fact that their role is to facilitate, not create communication and understand the importance of verbatim translation and that the interpreter does not intersperse ad-lib questions or edit the patient's responses. If the interpreter does not primarily work with psychiatric patients, it may be helpful to highlight the need for verbatim translation even if the responses are disorganized or contain unusual content. During the interview, the interpreter may slip into giving a sparse interpretation of longer speech productions. If this occurs, the interviewer should pause and ask the interpreter to offer everything the patient said and remind the interpreter of the request for verbatim interpretation.

To avoid the patient connecting more with the interpreter than the interviewer, one should arrange the parties' positions to allow the patient to maintain gaze in the direction of both interviewer and interpreter during the encounter. Interviewers need to be sensitive to the pace of questioning and parse out the questions and comments into smaller segments to allow the interpreter time to facilitate communication. Generally, more than one or two sentences or three complete thoughts is more than anyone, including interpreters, can hold accurately in memory to reproduce a verbatim translation once the interviewer stops speaking.

After the interview, the interpreter who is exceptionally knowledgeable about the patient's cultural background may be able to provide helpful insights and opinions about the nature of the patient's communication, for example, if a formal thought disorder was present and whether ideas the patient expressed were outside the norm for the cultural group.

The functionality of many telehealth applications allows grouping the patient, interviewer, and translator together.

Observed and Recorded Interviews

One-way mirror observation or recording of interviews occur in some settings for clinical, educational, or forensic purposes. Before initiating an observation or recording, the patient's informed consent for these activities must be precisely established. The patient should understand the purpose of observation or recording (e.g., psychotherapy, supervision), how it will be used, and who may have access to it (e.g., an attorney or other third parties in a forensic case). When recordings are made for clinical purposes, it should be clear how long the recording will be archived before being destroyed. If a recording is to be used for educational purposes, there are special informed consent considerations, including the patient's right to withdraw the consent and other matters beyond this chapter's scope. The clinician must ensure that the patient receives the same nature and quality of care in treatment settings regardless of whether consent to observe or record is granted.

Observation or recording of an interview can perturb the clinical interaction in expected and unexpected ways. Therefore, the clinician should remain vigilant for untended adverse effects on engagement and the free flow of information when interviews are observed or recorded.

Forensic Interviews

For this section, a forensic interview is defined as one taking place in a legal context for a purpose other than clinical treatment. For example, the psychiatrist may be retained by an insurance company to conduct an independent medical examination (IME) to offer an opinion in a disputed disability case, or by an attorney representing or prosecuting a defendant in a criminal case to offer opinions about competency to stand trial or criminal responsibility. Even in forensic settings where a psychiatrist is acting in a clinical role, for example, providing treatment in a correctional facility, some of the issues to be discussed here will apply.

Except for those providing clinical care in a forensic setting, forensic consultants do not technically form patient–doctor relationships with subjects, yet should still operate in these settings observing the ethical principles that apply and aspire to maintain the subject's dignity.

The agency or duty of the psychiatrist in the forensic setting is typically owed to a third party, for example, the attorney that retained the psychiatrist. Before proceeding with the interview, the subject should understand the agency of the psychiatrist and the boundaries of confidentiality. For example, when the psychiatrist is retained by the subject's defense attorney, confidential material is protected by the attorney–client privilege unless and until the attorney and client decide to use an opinion, at which point a report or testimony may be provided requiring a waiver of confidentiality to produce it. If the examiner is retained by a prosecuting attorney, an insurance company in an adversarial proceeding, or a judicial order demands a report, the subject waives confidentiality by agreeing to the examination. Some recent court decisions expand the rights of forensic subjects to confidentiality privileges under HIPAA that may require specific, informed consent and considerations about sharing of reports and other products of the evaluation. These matters are beyond the scope of this chapter, but those operating in these environments should educate themselves or consult legal counsel to ensure their practices align with requirements.

The principles of the forensic interview are built on the foundation of sound clinical practices though there are some critical differences. The level of detail required in a forensic consultation is typically greater than that sought in a general psychiatric interview. Forensic interviewing techniques require more detailed probing of the patient’s story and mental state that may sometimes require more clarification and even confrontation than typically utilized in a general psychiatric interview. Such interventions should be conducted in an ethically sound and sensitive manner. Collateral sources of information are critical to forensic examinations. These sources help discover vital elements of the history that the subject may not provide and serve to verify information offered by the subject externally. Forensic interviews are much more likely to be recorded than general psychiatric interviews and require special recording considerations beyond the scope of this chapter, but the subject must know when recording is occurring and understand who may have access to such recordings as part of the consent process. Psychiatrists engaging in forensic interviewing should have a clear sense of the boundaries of their training and experience and recognize the implications of their activities and the opinions they offer. Knowledge of the legal system (including the legal standards that apply to clinical questions), skills in specialized interviewing techniques, the role and proper application of psychological testing, and the vicissitudes of engaging with attorneys and courts are examples of the specialized information and skills that forensic settings demand.

Telepsychiatry

The advent of the COVID-19 pandemic forced mental health clinicians to quickly adopt and adapt to the use of telehealth technologies regardless of pre-existing attitudes about its utility. Previously, these technologies were primarily utilized in underserved areas where the geographic distance from or reliable access to providers made it unrealistic for the patient to come to a live appointment. Now telepsychiatry has emerged as an essential alternative means for access to care, safe and comfortable care delivery in the face of the COVID threat and appears to be here to stay as an alternative to in-person visits. Research and opinion leaders on the topic of telepsychiatry indicate that it is generally well accepted and a much more successful and viable alternative than most of us in the field may have predicted.

One must be cognizant that technology is not pristine enough to protect against some dropout of information usually gleaned in a live interview. Televised observation and communication can degrade nuances of speech, subtleties of the nature of eye contact, emotional display, body language, and other forms of nonverbal communication. Causes of information degradation include the narrow perspective of the camera, the quality of the audio-visual product, and the unexplained effects that humans have on one another in a live interaction that are not entirely replicated in a distance medium. On the other hand, the availability of telehealth has expanded many patients' access to care, and many patients find the medium a more comfortable means to discuss difficult topics and appreciate the logistical advantage that reduces time off work, travel and waiting time, childcare challenges, and the like. Some others do not adapt to the virtual visit, and still, others may not have the right technology or facility with technology to use the medium effectively. Many of us who have utilized the technologies have come to appreciate that we are now essentially doing home visits and learning so much more about the patient's environments than we ever did before. It also makes meetings between the collaterals and the patient possible in logistically challenging cases, for example, the student at college and the parent at home.

The American Telemedicine Association and the American Medical Association are associations that collaborate with other professional organizations to develop evidence-based guidelines promoting quality and safe practices for various telemedicine applications, including telepsychiatry. Clinicians engaging in telemedicine are advised to familiarize themselves with the special considerations that this medium introduces, including medical-legal and reimbursement issues. Interstate use of telehealth is generally forbidden without special waivers or licensing considerations that vary from state to state.

7.2 The Psychiatric Report and Outline for a Psychiatric Examination

Benjamin J. Sadock, M.D.

The psychiatric history and the mental status are to the psychiatrist what the medical history and physical examination are to the internist. The psychiatric history describes life events from infancy to old age to the extent they can be recalled. It is sometimes called the *anamnesis* (from the Greek meaning “to remember”). The mental status covers how the patient appears and the thoughts and feelings evoked as he or she responds to specific questions asked by the examiner.

The psychiatric report is more than the psychiatric history and mental status. It not only includes those components it also includes a summary of positive and negative findings and an interpretation of the data found, thereby providing an understanding of the case. The report also addresses critical questions: Are future diagnostic studies needed, and, if so, which ones? Is a comprehensive neurologic workup, including an electroencephalogram (EEG) or imaging studies, needed? Are psychological tests indicated? Are psychodynamic factors relevant? The report includes a diagnosis made according to the latest edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). A prognosis is also discussed in the report, with good and bad prognostic factors listed. The report concludes with a discussion of a treatment plan and makes firm recommendations about the management of the case.

The outline for the psychiatric examination that follows was developed by the author and Harold Kaplan, MD. It has been used by countless numbers of psychiatrists over several generations and has been revised and updated periodically, especially for this edition. It includes a tremendous amount of information about the patient; however, not all need to be obtained depending on circumstances in the case. Beginning clinicians are advised to get as much information as possible; more experienced clinicians can pick and choose among the series of questions they might ask. In all cases, the person is best understood within the context of their life events.

PSYCHIATRIC HISTORY

A. *Identification:* Name; age; marital status; sex; occupation; language, if other than English; race and ethnic origin; nationality; religion; and persons with whom the patient lives.

B. *Chief complaint:* Exactly why the patient came to the psychiatrist, preferably in the patient’s own words; if that information does not come from the patient, note who supplied it.

C. *History of present illness:* Chronologic background and development of the symptoms or behavioral changes that culminated in the patient's seeking assistance; patient's life circumstances at the time of onset; personality when well; how illness has affected life activities and personal relations—changes in personality, interests, mood, attitudes toward others, dress, habits, level of tenseness, irritability, activity, attention, concentration, memory, speech; psychophysiologic symptoms—nature and details of dysfunction; pain—location, intensity, and fluctuation; level of anxiety—generalized and nonspecific (free-floating) or specifically related to particular situations, activities, or objects; how anxieties are handled—avoidance, repetition of a feared situation, or use of drugs or other activities for alleviation.

D. *Past psychiatric and medical history:* (1) Emotional or mental disturbances—extent of incapacity, type of treatment, names of hospitals, length of illness, and effect of treatment; (2) physical disorders—allergies, arthritis, colitis, chronic fatigue, recurrent colds, and skin conditions; (3) medical conditions—customary review of systems, sexually transmitted diseases, alcohol or other substance abuse, or at risk for acquired immunodeficiency syndrome (AIDS); (4) neurologic disorders—headache, craniocerebral trauma, loss of consciousness, seizures, or tumors (5) Vaccinations—smallpox, DPT, flu, Covid.

E. *Family history:* Elicited from the patient and from someone else if possible because quite different descriptions may be given of the same people and events; ethnic, national, and religious traditions; other people in the home, descriptions of them—personality and intelligence—and what has become of them since the patient's childhood; descriptions of different households lived in; present relationships between the patient and those who are in the patient's family; the role of illness in the family; family history of mental illness; where does the patient live—neighborhood and particular residence of the patient; is the home crowded; privacy of family members from each other and from other families; sources of family income and difficulties in obtaining it; public assistance (if any) and attitudes about it; will the patient lose their job or apartment by remaining in the hospital; who is caring for the patient's children.

F. *Personal history:* History of the patient's life from infancy to the present to the extent it can be recalled; gaps in history as spontaneously related by the patient; emotions associated with different life periods (painful, stressful, and conflictual) or with phases of the life cycle.

1. Early childhood to the extent it can be recalled or about which patient was told (through 3 years of age).
    - a. Prenatal history and mother's pregnancy and delivery: Length of pregnancy, spontaneity, and normality of delivery, birth trauma, whether the patient was planned and wanted, birth defects.
    - b. Feeding habits: Breastfed or bottle-fed, eating problems.
    - c. Early development: Maternal deprivation, language development, motor development, signs of unmet needs, sleep pattern, object constancy, stranger anxiety, separation anxiety.
    - d. Toilet training: Age, the attitude of parents, feelings about it.
    - e. Symptoms of behavior problems: Thumb sucking, temper tantrums, tics, head bumping, rocking, night terrors, fears, bed-wetting or bed-soiling, nail-biting.
    - f. Personality and temperament as a child: Shy, restless, overactive, withdrawn, studious, outgoing, timid, athletic, friendly, patterns of play, reactions to siblings.
    - g. Early or recurrent dreams or fantasies.
2. Middle childhood (3 to 11 years of age): Early school history—feelings about going to school, early adjustment, gender identification, conscience development, punishment, social relationships, and attitudes toward siblings and playmates.
3. Later childhood (prepuberty through adolescence).
    - a. Peer relationships: Number and closeness of friends, leader or follower, social popularity, participation in group or gang activities, idealized figures; patterns of aggression, passivity, anxiety, antisocial behavior.
    - b. School history: How far the patient went in school; adjustment to school; relationships with teachers—teacher's pet or

rebellious; favorite studies or interests; particular abilities or assets; extracurricular activities; sports; hobbies; relationships; problems or symptoms in any school period. School history can be extended to college in this section.

- c. Cognitive and motor development: Learning to read and other intellectual and motor skills, minimal cerebral dysfunction, learning disabilities—their management and effects on the child.
- d. Particular adolescent emotional or physical problems: Nightmares, phobias, bed-wetting, running away, delinquency, smoking, drug or alcohol use, weight problems, feeling of inferiority.
- e. Psychosexual history.
  - i. Early curiosity, infantile masturbation, sex play.
  - ii. Acquiring of sexual knowledge, attitude of parents toward sex, sexual abuse.
  - iii. Onset of puberty, feelings about it, kind of preparation, feelings about menstruation, development of secondary sexual characteristics.
  - iv. Adolescent sexual activity: Crushes, parties, dating, petting, masturbation, wet dreams (nocturnal emissions), and attitudes toward them.
  - v. Attitudes toward same and opposite sex: Timid, shy, aggressive, need to impress, seductive, anxious.
  - vi. Sexual practices: Sexual problems, homosexual and heterosexual experiences, paraphilias, promiscuity.
- f. Religious background: Strict, liberal, mixed (possible conflicts), the relationship of background to current religious practices.

4. Adulthood.
   - a. Occupational history: Choice of occupation, training, ambitions, and conflicts; relations with authority, peers, and subordinates; the number of jobs and duration; changes in job status; current job and feelings about it.
   - b. Social activity: Whether the patient has friends; whether he or she is withdrawn or socializing well; social, intellectual, and

physical interests; relationships with same-sex and opposite sex; depth, duration, and quality of human relations.

c. Adult sexuality.
   i. Premarital sexual relationships, age of first coitus, sexual orientation, gender confusion.
   ii. Marital history: Common-law marriages; legal marriages; description of courtship and role played by each partner; age at marriage; family planning and contraception; names and ages of children; attitudes toward raising children; problems of any family members; housing difficulties, if important to the marriage; sexual adjustment; extramarital affairs; areas of agreement and disagreement; management of money; the role of in-laws.
   iii. Sexual symptoms: Anorgasmia, erectile disorder, premature ejaculation, lack of desire.
   iv. Sexual practices: Paraphilias, such as sadism, fetishes, voyeurism; attitude toward fellatio, cunnilingus; coital techniques, frequency.

d. Military history: General adjustment, combat, injuries, referral to psychiatrists, type of discharge, veteran status.

e. Value systems: Whether children are seen as a burden or a joy; whether work is seen as a necessary evil, an avoidable chore, or an opportunity; current attitude about religion; belief in heaven and hell; attitudes toward pregnancy and having children; contraceptive practices and feelings about them.

MENTAL STATUS

Sum total of the examiner's observations and impressions derived from the initial interview.

A. Appearance.

1. Personal identification: May include a brief, nontechnical description of the patient's appearance and behavior as a novelist might write it. Attitude toward examiner can be described here: cooperative, attentive, interested, frank, seductive, defensive, hostile, playful, ingratiating, evasive, or guarded.

    2. Behavior and psychomotor activity: Gait, mannerisms, tics, gestures, twitches, stereotypes, picking, touching examiner, echopraxia, clumsy, agile, limp, rigid, retarded, hyperactive, agitated, combative, or waxy.
    3. General description: Posture, bearing, clothes, grooming, hair, nails; healthy, sickly, angry, frightened, apathetic, perplexed, contemptuous, ill at ease, poised, old looking, young-looking, effeminate, masculine; signs of anxiety—moist hands, perspiring forehead, restlessness, tense posture, strained voice, wide eyes; shifts in the level of anxiety during the interview or with a particular topic; eye contact (50% is normal).

B. *Speech:* Rapid, slow, pressured, hesitant, emotional, monotonous, loud, whispered, slurred, mumbled, stuttering, echolalia, intensity, pitch, ease, spontaneity, productivity, manner, reaction time, vocabulary, prosody.

C. Mood and affect.

    1. Mood (a pervasive and sustained emotion that colors the person's perception of the world): How does patient say he or she feels; depth, intensity, duration, and fluctuations of mood—depressed, despairing, irritable, anxious, terrified, angry, expansive, euphoric, empty, guilty, awed, futile, self-contemptuous, anhedonic, alexithymic. Suicide: ideas, plans, ruminations, or obsessions about, previous attempts.
    2. Affect (the outward expression of the patient's inner experiences): How the examiner evaluates the patient's affects—broad, restricted, blunted, flat, shallow, amount and range of expression; difficulty in initiating, sustaining, or terminating an emotional response; whether the emotional expression is appropriate to the thought content, culture, and setting of the examination; examples should be given if the emotional expression is not appropriate.

D. Thinking and perception.

    1. Form of thinking.
        a. Productivity: Overabundance of ideas, paucity of ideas, flight of ideas, rapid thinking, slow thinking, hesitant thinking; whether the patient speaks spontaneously or only when questions are asked; the stream of thought, quotations from the patient.

    - b. Continuity of thought: Whether the patient’s replies really answer questions and are goal-directed, relevant, or irrelevant; loose associations; lack of cause-and-effect relationships in the patient’s explanations; illogical, tangential, circumstantial, rambling, evasive, persevering statements, blocking or distractibility.
    - c. Language impairments: Impairments that reflect disordered mentation, such as incoherent or incomprehensible speech (word salad), clang associations, neologisms.
  - 2. Content of thinking.
    - a. Preoccupations: About the illness, environmental problems; obsessions, compulsions, phobias; thoughts of harming others, specific antisocial urges or impulses.
  - 3. Thought disturbances.
    - a. Delusions: Content of any delusional system, its organization, the patient’s convictions as to its validity, how it affects their life; persecutory delusions—isolated or associated with pervasive suspiciousness; mood-congruent or mood-incongruent; thought insertion.
    - b. Ideas of reference and ideas of influence: How ideas began, their content, and the meaning that the patient attributes to them.
  - 4. Perceptual disturbances.
    - a. Hallucinations and illusions: Whether the patient hears voices or sees visions; content, sensory system involvement, circumstances of the occurrence; hypnagogic or hypnopompic hallucinations; thought broadcasting or thought insertion, disturbances in smell.
    - b. Depersonalization and derealization: Extreme feelings of detachment from self or from the environment.
  - 5. Dreams and fantasies.
    - a. Dreams: Prominent ones, if the patient will tell them; nightmares.
    - b. Fantasies: Recurrent, favorite, or unshakable daydreams.
- E. Sensorium.

1. Alertness: awareness of the environment, attention span, clouding of consciousness, fluctuations in levels of awareness, somnolence, stupor, lethargy, fugue state, coma.
2. Orientation.
   a. Time: Whether the patient identifies the day or the approximate date and the time of day correctly; if in a hospital, whether the patient knows how long he or she has been there; whether the patient behaves as though oriented to the present.
   b. Place: Whether patient knows where he or she is.
   c. Person: Whether the patient knows who the examiner is and the roles or names of the persons with whom the patient is in contact.
3. Concentration and calculation: Whether the patient can subtract 7 from 100 and keep subtracting 7s; if the patient cannot subtract 7s, whether easier tasks can be accomplished, such as 4 × 9 and 5 × 4; whether the patient can calculate how many nickels are in $1.35; whether anxiety or some disturbance of mood or concentration seems to be responsible for difficulty.
4. Memory: Impairment, efforts made to cope with impairment—denial, confabulation, catastrophic reaction, circumstantiality used to conceal deficit; whether the process of registration, retention, or recollection of material is involved.
   a. Remote memory: Childhood data, important events known to have occurred when the patient was younger or free of illness, personal matters, neutral material.
   b. Recent past memory: Past few months.
   c. Recent memory: Past few days, what did the patient do yesterday and the day before, what did the patient have for breakfast, lunch, and dinner.
   d. Immediate retention and recall: Ability to repeat six figures after the examiner dictates them—first forward, then backward, then after a few minutes' interruptions; other test questions; whether the same questions, if repeated, called forth different answers at different times.
   e. Effect of defect on the patient: Mechanisms the patient has developed to cope with the defect.

5. Fund of knowledge: Level of formal education and self-education; estimate of the patient's intellectual capability and whether the patient is capable of functioning at the level of their basic endowment; counting, calculation, general knowledge; questions should have relevance to the patient's educational and cultural background.
6. Abstract thinking: Disturbances in concept formation; the manner in which the patient conceptualizes or handles their ideas; similarities (e.g., between apples and pears), differences, absurdities; meanings of simple proverbs, such as "a rolling stone gathers no moss"; answers may be concrete (giving specific examples to illustrate the meaning) or overly abstract (giving generalized explanation); appropriateness of answers.
7. Insight: Degree of personal awareness and understanding of illness.
   a. Complete denial of illness.
   b. Slight awareness of being sick and needing help but denying it at the same time.
   c. Awareness of being sick but blaming it on others or external factors, or on medical or unknown organic factors.
   d. Intellectual insight: Admission of illness and recognition that symptoms or failures in social adjustment are due to irrational feelings or disturbances, without applying that knowledge to future experiences.
   e. True emotional insight: Emotional awareness of the motives and feelings within and of the underlying meaning of symptoms; whether the awareness leads to changes in personality and future behavior; openness to new ideas and concepts about self and the important people in the patient's life.
8. Judgment.
   a. Social judgment: Subtle manifestations of behavior that are harmful to the patient and contrary to acceptable behavior in the culture; whether the patient understands the likely outcome of personal behavior and is influenced by that understanding; examples of impairment.
   b. Tests of judgment: The patient's prediction of what he or she would do in imaginary situations; for instance, what the patient

would do with a stamped, addressed letter found in the street.

FURTHER DIAGNOSTIC STUDIES

A. Physical examination.
B. Neurologic examination.
C. Additional psychiatric diagnostic interviews.
D. Interviews with family members, friends, or neighbors by a social worker.
E. Psychological, neurologic, or laboratory tests, as indicated: EEG, CT scan, magnetic resonance imaging (MRI), tests of other medical conditions (e.g., human immunodeficiency virus [HIV]), reading comprehension and writing tests, test for aphasia, projective or objective psychological tests, dexamethasone-suppression test (DST), 24-hour urine test for heavy metal intoxication, urine screen for drugs of abuse, sleep studies in chronic insomnia.

SUMMARY OF FINDINGS

Mental symptoms, medical and laboratory findings, and psychological and neurologic test results, if available, are summarized. Include the medications that the patient has been taking, their dosage, and their duration.

Table 7.2–1.

Common Questions for the Psychiatric History and Mental Status

Topic	Questions	Comments and Helpful Hints
Identifying data: Name, age, sex, marital status, religion, education, address, phone number, occupation, source of referral	Be direct in obtaining identifying data. Request specific answers.	If patient cannot cooperate, get information from family member or friend; if referred by a physician, obtain medical record.
Chief complaint (CC): Brief statement in patient's own words of why patient is in the hospital or is being seen in consultation	Why are you going to see a psychiatrist? What brought you to the hospital? What seems to be the problem?	Record answers verbatim; a bizarre complaint points to psychotic process.
History of present illness (HPI): Development of symptoms from time of onset to present; relation of life events, conflicts, stressors: drugs; change from previous level of functioning	When did you first notice something happening to you? Were you upset about anything when symptoms began? Did they begin suddenly or gradually?	Record in patient's own words as much as possible. Get history of previous hospitalizations and treatment. Sudden onset of symptoms may indicate drug-induced disorder.
Previous psychiatric and medical	Did you ever lose consciousness? Have a	Ascertain extent of illness, treatment,

disorders: Psychiatric disorders; psychosomatic; medical, neurologic illnesses (e.g., craniocerebral trauma, convulsions)	seizure?	medications, outcomes, hospitals, doctors. Determine whether illness serves some additional purpose (secondary gain).
Personal history: Birth and infancy: To the extent known by the patient, ascertain mother’s pregnancy and delivery, planned or unwanted pregnancy, developmental landmarks—standing, walking, talking, temperament	Do you know anything about your birth? If so, from whom? How old was your mother when you were born? Your father?	Older mothers (>35 years) have high risk for Down syndrome baby; older father (>45 years) may contribute damaged sperm-producing deficits including schizophrenia.
Childhood: Feeding habits, toilet training, personality (shy, outgoing), general conduct and behavior, relationship with parents or caregivers and	Toilet training? Bed-wetting? Sex play with peers? What is your first childhood memory?	Separation anxiety and school phobia associated with adult depression; enuresis associated with fire setting. Childhood memories before the age of 3 are

peers, separations, nightmares, bed-wetting, fears		usually imagined, not real.
Adolescence: Peer and authority relationship, school history, grades, emotional problems, drug use, age of puberty	Adolescents may refuse to answer questions, but they should be asked. Adults may distort memories of emotionally charged adolescent experience. Sexual molestation?	Poor school performance is a sensitive indicator of emotional disorder. Schizophrenia begins in late adolescence.
Adulthood: Work history, choice of career, marital history, children, education, finances, military history, religion	Open-ended questions are preferable. Tell me about your marriage. Be nonjudgmental: What role does religion play in your life, if any? What is your sexual preference in a partner?	Depending on CC some areas require more detailed inquiry. Manic patients frequently go into debt or are promiscuous. Overvalued religious ideas associated with paranoid personality disorder.
Sexual history: Sexual development, masturbation, anorgasmia, erectile disorder, premature ejaculation, paraphilia, sexual	Are there or have there been any problems or concerns about your sex life? How did you learn about sex? Has there been any change in your sex drive?	Be nonjudgmental. Asking *when* masturbation began is a better approach than asking *do you* or *did you ever* masturbate.

orientation, general attitudes, and feelings		
Family history: Psychiatric, medical, and genetic illness in mother, father, siblings; age of parents and occupations; if deceased, date and cause; feelings about each family member, finances	Have any members in your family been depressed? Alcoholic? In a mental hospital? In jail? Describe your living conditions. Did you have your own room?	Genetic loading in anxiety, depression, schizophrenia. Get medication history of family (medications effective in family members for similar disorders may be effective in patient).
Mental Status		
General appearance: Note appearance, gait, dress, grooming (neat or unkempt), posture, gestures, facial expressions. Does patient appear older or younger than stated age?	Introduce yourself and direct patient to take a seat. In the hospital, bring your chair to bedside; do not sit on the bed.	Unkempt and disheveled in cognitive disorder; pinpoint pupils in narcotic addiction; withdrawal and stooped posture in depression.
Motoric behavior: Level of activity: Psychomotor agitation or psychomotor	Have you been more active than usual? Less active? You may ask about obvious mannerisms, e.g., “I	Fixed posturing, odd behavior in schizophrenia. Hyperactive with stimulant

retardation—tics, tremors, automatisms, mannerisms, grimacing, stereotypes, negativism, apraxia, echopraxia, waxy flexibility; emotional appearance—anxious, tense, panicky, bewildered, sad, unhappy: voice—faint, loud, hoarse; eye contact	notice that your hand still shakes, can you tell me about that?” Stay aware of smells, e.g., alcoholism/ketoacidosis.	(cocaine) abuse and in mania. Psychomotor retardation in depression; tremors with anxiety or medication side effect (lithium). Eye contact is normally made approximately half the time during the interview. Minimal eye contact in schizophrenia. Scanning of environment in paranoid states.
Attitude during interview: How patient relates to examiner—irritable, aggressive, seductive, guarded, defensive, indifferent, apathetic, cooperative, sarcastic	You may comment about attitude: You seem irritated about something; is that an accurate observation?	Suspiciousness in paranoia; seductive in hysteria; apathetic in conversion disorder (*la belle indifference*); punning (*witzlesucht*) in frontal lobe syndromes.
Mood: Steady or sustained emotional state—	How do you feel? How are your spirits? Do you have thoughts that life is	Suicidal ideas in 25% of depressives;

gloomy, tense, hopeless, ecstatic, resentful, happy, bashful, sad, exultant, elated, euphoric, depressed, apathetic, anhedonic, fearful, suicidal, grandiose, nihilistic	not worth living or that you want to harm yourself? Do you have plans to take your own life? Do you want to die? Has there been a change in your sleep habits?	elation in mania. Early morning awakening in depression; decreased need for sleep in mania.
Affect: Feeling tone associated with idea—labile, blunt, appropriate to content, inappropriate, flat	Observe nonverbal signs of emotion, body movements, facies, rhythm of voice (prosody). Laughing when talking about sad subjects, e.g., death, is inappropriate.	Changes in affect usual with schizophrenia: loss of prosody in cognitive disorder, catatonia. Do not confuse medication adverse effect with flat affect.
Speech: Slow, fast, pressured, garrulous, spontaneous, taciturn, stammering, stuttering, slurring, staccato. Pitch, articulation, aphasia, coprolalia, echolalia, incoherent,	Ask patient to say “Methodist Episcopalian” to test for dysarthria.	Manic patients show pressured speech; paucity of speech in depression; uneven or slurred speech in cognitive disorders.

logorrhea, mute, paucity, stilted		
Perceptual disorders: Hallucinations—olfactory, auditory, haptic (tactile), gustatory, visual; illusions; hypnopompic or hypnagogic experiences; feeling of unreality, *déjà vu, éjà entendu,* macropsia	Do you ever see things or hear voices? Do you have strange experiences as you fall asleep or upon awakening? Has the world changed in any way? Do you have strange smells?	Visual hallucinations suggest schizophrenia. Tactile hallucinations suggest cocainism, delirium tremens (DTs). Olfactory hallucinations common in temporal lobe epilepsy.
Thought content: Delusions—persecutory (paranoid), grandiose, infidelity, somatic, sensory, thought broadcasting, thought insertion, ideas of reference, ideas of unreality, phobias, obsessions, compulsions, ambivalence, autism, dereism, blocking, suicidal or homicidal	Do you feel people want to harm you? Do you have special powers? Is anyone trying to influence you? Do you have strange body sensations? Are there thoughts that you can’t get out of your mind? Do you think about the end of the world? Can people read your mind? Do you ever feel the TV is talking to you? Ask about fantasies and dreams.	Are delusions congruent with mood (grandiose delusions with elated mood) or incongruent? Mood-incongruent delusions point to schizophrenia. Illusions are common in delirium. Thought insertion is characteristic of schizophrenia.

preoccupation, conflicts, nihilistic ideas, hypochondriasis, depersonalization, derealization, flight of ideas, *idé* fixe, magical thinking, neologisms		
Thought process: Goal-directed ideas, loosened associations, illogic, tangential, relevant, circumstantial, rambling, ability to abstract, flight of ideas, clang associations, perseveration	Ask meaning of proverbs to test abstraction, e.g., “People in glass houses should not throw stones.” Concrete answer is, “Glass breaks.” Abstract answers deal with universal themes or moral issues. Ask similarity between bird and butterfly (both alive), bread and cake (both food).	Loose associations point to schizophrenia; flight of ideas, to mania; inability to abstract, to schizophrenia, brain damage.
Sensorium: Level of consciousness—alert, clear, confused, clouded, comatose, stuporous; orientation to time, place, person; cognition	What place is this? What is today’s date? Do you know who I am? Do you know who you are?	Delirium or dementia shows clouded or wandering sensorium. Orientation to person remains intact longer than orientation to time or place.
Memory: Remote	Where were you born?	Patients with

memory (long term): Past several days, months, years	Where did you go to school? Date of marriage? Birthdays of children? What were last week's newspaper headlines?	dementia of the Alzheimer type retain remote memory longer, than recent memory. Gaps in memory may be localized or filled in with confabulatory details. Hypermnesia is seen in paranoid personality.
Recent memory (short term): Recall of events in past day or two	Where were you yesterday? What did you eat at your last meal?	In brain disease, recent memory loss (amnesia) usually occurs before remote memory loss.
Immediate memory (very short term): Laying down of immediate information with ability to quickly recall data	Ask patient to repeat six digits forward, then backward (normal responses). Ask patient to try to remember three nonrelated items; test patient after 5 minutes.	Loss of memory occurs with cognitive, dissociative, or conversion disorder. Anxiety can impair immediate retention and recent memory. Anterograde memory loss (amnesia) occurs after taking certain drugs, e.g.,

		benzodiazepines. Retrograde memory loss occurs after head trauma.
Concentration and calculation: Ability to pay attention; distractibility; ability to do simple math	Ask patient to count from 1 to 20 rapidly; do simple calculations (2 × 3, 4 × 9); do serial 7 test, i.e., subtract 7 from 100 and keep subtracting 7. How many nickels in $1.35?	Rule out medical cause for any defects vs. anxiety or depression (pseudodementia). Make tests congruent with educational level of patient.
Information and intelligence: Use of vocabulary; level of education; fund of knowledge	Distance from New York City to Los Angeles. Name some vegetables. What is the largest river in the United States?	Check educational level to judge results. Rule out mental retardation, borderline intellectual functioning.
Judgment: Ability to understand relations between facts and to draw conclusions; responses in social situations	What is the thing to do if you find an envelope in the street that is sealed, stamped, and addressed?	Impaired in brain disease, schizophrenia, borderline intellectual functioning, intoxication.
Insight level: Realizing that there are physical or mental problems; denial of illness, ascribing blame to	Do you think you have a problem? Do you need treatment? What are your plans for the future?	Impaired in delirium, dementia, frontal lobe syndrome, psychosis, borderline intellectual functioning.

outside factors;
recognizing need
for treatment

DIAGNOSIS

Diagnostic classification is made according to the DSM.

PROGNOSIS

Opinion about the probable future course, extent, and outcome of the disorder; good and bad prognostic factors; specific goals of therapy.

PSYCHODYNAMIC FORMULATION

Causes of the patient’s psychodynamic breakdown—influences in the patient’s life that contributed to the present disorder, environmental, genetic, and personality factors relevant to determining the patient’s symptoms; primary and secondary gains; outline of the major defense mechanism used by the patient.

COMPREHENSIVE TREATMENT PLAN

Modalities of treatment recommended role of medication, inpatient or outpatient treatment, frequency of sessions, probable duration of therapy; type of psychotherapy; individual, group, family, or cognitive-behavioral therapy among others; symptoms or problems to be treated. Initially, treatment must be directed toward any life-threatening situations, such as suicidal risk or risk of danger to others, which require psychiatric hospitalization. Danger to self or others is an acceptable reason (legally and medically) for involuntary hospitalization. In the absence of the need for confinement, a variety of outpatient treatment alternatives are available: Day hospitals, supervised residences, outpatient psychotherapy, or pharmacotherapy. In some cases, treatment planning must attend to vocational and psychosocial skills training and even legal or forensic issues. Comprehensive treatment planning requires a therapeutic team approach using the skills of psychologists, social workers, nurses, activity and occupational therapists, and a variety of other mental health professionals, with referral to self-help groups (e.g., Alcoholics Anonymous [AA]) if needed. If the patient or family members are unwilling to accept the recommendations of treatment and the clinician thinks that the refusal of the recommendations may have serious consequences, then the patient, parent, or guardian should sign a statement to the effect that the recommended treatment was refused.

Finally, clarity of thinking is reflected in the clarity of writing. Avoid run-on sentences. Use the active voice as much as possible. Be precise. When summarizing the mental status, for example, the phrase “patient denies hallucinations and delusions” is not as precise as “patient denies hearing voices or thinking that he is being followed.” The latter indicates the specific question asked and the specific response given. Then, at the conclusion of the report, one would write, “Hallucinations and delusions were not elicited.” This is consistent with the principle stated above: Use the patient’s words—and those of the examiners—as much as possible.

In Table 7.2–1, the reader will find sample questions to be used in eliciting data for the psychiatric history and mental status, along with comments and helpful hints about their clinical significance.

7.3 Practice Guidelines in Psychiatry

Laura J. Fochtmann, M.D., M.B.I., and John S. McIntyre, M.D.

Over the past half century there have been great advances in the knowledge base for all of medicine including psychiatry. Much has been learned about the etiology and epidemiology of mental illnesses and the efficacy and effectiveness of treatments. Evidence-based medicine is the process of translating those advances into the day-to-day care of patients. However, a large number of studies and reports have documented that effective interventions are not always implemented in a timely fashion, if at all. Compounding this problem, especially in the United States, is the reality that reimbursement for services is not necessarily driven by what has been shown to be optimal care. These issues can be addressed using practice guidelines, which are sets of evidence-based strategies that are aimed at assisting physicians and patients in clinical decision making and improving care.

EARLY GUIDELINE EFFORTS

Throughout the history of medicine there have been recommendations for the care of patients, which have been promulgated orally or in written form. In 1851, 7 years after its founding, the American Association of Medical Superintendents of Hospitals for the Insane (later to become the American Psychiatric Association [APA]) issued 26 propositions concerning “the construction of hospitals for the insane.” Two years later 14 propositions concerning the organization of these facilities were published. These propositions were intended to provide guidance about psychiatric care but did not include documentation of the evidence behind the propositions or the process by which they were developed. Early efforts at promulgating evidence-based guidelines in the United States included the publications of the American Academy of Pediatrics on immunizations in the 1940s. Over the subsequent four decades the number of guidelines began to increase and by the mid-1980s the growth had become exponential.

AMERICAN MEDICAL ASSOCIATION AND GUIDELINES

In the late 1980s the American Medical Association (AMA) convened a group of representatives from 14 medical specialty organizations, including the APA. Also attending on a regular basis were representatives from the Agency for Health Care Policy and Research, Joint Commission on Accreditation of Health Care Organizations, American Hospital Association, National Council on Quality Assurance, and the Health Care Financing Administration. This consortium was initially named the Practice Parameter Partnership and later renamed the Practice Guideline Partnership. In 1989, the Partnership described five recommended attributes of guidelines: (1) be developed by or in conjunction with physician organizations, (2) use reliable methodologies that integrate relevant research findings and clinical expertise, (3) be as comprehensive and specific as possible, (4) be based on current information, (5) be widely disseminated. In 1996, a sixth attribute was added: Guideline development should include outcomes research, goals, and measures. The focus on measures was spurred by the increased interest in assessing whether guidelines were followed and led to the development of the AMA-led Physician Consortium for Performance Improvement (PCPI).

In 1999, the AMA and the American Association of Health Plans collaborated with the Agency for Healthcare Research and Quality (AHRQ) of the U.S. Department of Health and Human Service in establishing the web-based National Guidelines Clearinghouse.

INSTITUTE OF MEDICINE REPORTS

In parallel with the increasing involvement of professional organizations in developing practice guidelines, the Institute of Medicine (IOM) began to discuss and define optimal characteristics of practice guidelines. In 1990, the IOM published a monograph: *Clinical Practice Guidelines—Directions for a New Program*. Incorporating some of the recommendations included in the AMA report, “good guidelines” were identified as having eight attributes as identified in Table 7.3–1.

This IOM report describes practice guidelines as “valid if, when followed, they lead to the health and cost outcomes projected for them, other things being equal.” Practice guidelines are defined as “reliable and reproducible” if a different group of developers, given the same evidence and using the same methods, arrive at the same recommendations and if the guidelines are interpreted and applied consistently by clinicians in similar settings. “Clinical applicability” requires that the population being treated with the guideline be explicitly identified. A guideline has “flexibility” if the generally expected exceptions are identified and “clarity” if terms are well defined and unambiguous language is used. The report indicates that a “multidisciplinary process” may include “[participants from different disciplines] serving on panels that develop guidelines, providing evidence and viewpoints to the panels and reviewing draft guidelines.” The report also notes that practice guidelines should include specific plans about “review and revision” schedules and that there should be “meticulous documentation and description” of the evidence used, the process followed, and the individuals involved in developing guidelines.

Scheduled review
Documentation

Data from Field MJ, Lohr KN, eds. *Clinical Practice Guidelines—Directions for a New Program*. National Academies Press; 1990.

Two decades later, a series of IOM reports expanded on these recommendations for practice guideline development. A 2008 report, *Knowing What Works in Health Care: A Road Map for the Nation*, described the reasons that changes were needed in synthesizing of information and using it for clinical decisions. The report cited information overload and health policy challenges such as unsustainable health care costs and geographic variations in the amount and quality of care. It also noted that available systematic reviews and clinical practice guidelines had not fulfilled their original promise due to a lack of universal development standards, variations in evidence appraisal, and inconsistent handling of conflicts of interest. This report served as the impetus for the Medicare Improvements for Patients and Providers Act of 2008 to request two additional IOM reports, *Finding What Works in Health Care: Standards for Systematic Reviews* and *Clinical Practice Guidelines We Can Trust*.

For systematic reviews, the IOM gives 21 recommendations to promote objectivity, transparency, and reliability in the review process. These recommendations include, but are not limited to, establishing a systematic review team with the appropriate expertise and experience, managing bias and conflict of interest among team members and those providing input into the review, obtaining public input on the review at multiple steps in the process, developing a protocol for the review that is established a priori, and using clear and transparent processes for a comprehensive search and for evidence review and synthesis. In the complementary report on clinical practice guidelines, the IOM gives eight additional recommendations that discuss the importance of transparency and management of conflict of interest, appointing a balanced multidisciplinary guideline development group, using rigorously conducted systematic reviews, providing ratings of the strength of recommendations based on the underlying quality of available evidence, and wording guideline recommendations in precise actionable terms. The IOM also notes that practice guidelines should be subjected to public review and regular updating. Many of these precepts of guideline development were subsequently affirmed by the Council of Medical Specialty Societies in their “Principles for the Development of Specialty Society Clinical Guidelines.”

PRACTICE GUIDELINES IN PSYCHIATRY

One of the first psychiatric associations to publish guidelines was the Royal Australian and New Zealand College of Psychiatrists (RANZCP) beginning in 1981. This project initially had a unique methodology for blending research findings and clinical consensus. A group of research experts developed a guideline for a particular disorder and a group of clinicians developed a guideline for the same disorder and then the two guidelines were integrated into a single document.

Other psychiatric guideline efforts soon followed. In the United States, the APA has been developing guidelines since 1989 (https://www.psychiatry.org/psychiatrists/practice/clinical-practice-guidelines), and the American Academy of Child and Adolescent Psychiatry (AACAP) published its initial Practice Parameters in 1991 (http://www.jaacap.com/content/pracparam). The Veterans Administration also has a robust guideline development process, which includes psychiatric guidelines (http://www.healthquality.va.gov/). Other agencies and professional organizations that have developed guidelines of relevance to psychiatry include, but are not limited to, the American College of Physicians, the American Psychological Association, the Canadian Psychiatric Association, Canadian Network for Mood and Anxiety Treatments, The National Institute for Health and Care Excellence (NICE), the Scottish Intercollegiate Guidelines Network, and The World Federation of Societies of Biological Psychiatry.

APA PRACTICE GUIDELINE PROJECT

History

The APA Practice Guideline project began in 1989. An action paper in the APA Assembly called for the APA to develop practice guidelines to assist psychiatrists in their care of patients. Following approval by the APA Board of Trustees (BOT) and President, a Steering Committee was formed to create a process to develop guidelines and provide ongoing oversight.

Guideline Committees and Writing Groups

Early in the APA project, the decision was made that no industry money would be sought or accepted for the guideline development. In addition, writing group and practice guideline committee members are carefully screened for potential conflicts of interest in order to limit the risk of bias in guideline recommendations. Several APA staff, including the medical editor of the guidelines, have been assigned to the project. With their participation and the volunteer efforts of countless work group members and committee members, the project has continued to flourish.

Based upon the recommendations of the IOM, guidelines are written by a multidisciplinary group of individuals, some of whom have specific expertise on the guideline topic but others of whom have more general expertise in the treatment of psychiatric disorders.

Choosing a Topic

The initial step in developing a guideline is to choose a topic. At the onset of the APA project it was decided to develop guidelines for specific illnesses/disorders as defined by the *Diagnostic and Statistical Manual of Mental Disorders*. Having a criteria-based diagnostic nomenclature was a major asset in starting the project. More recently, some guidelines have addressed more circumscribed topics in patients with a given diagnosis, such as treatment of specific symptoms (e.g., agitation or psychosis in patients with dementia) or use of specific types of treatment (e.g., pharmacotherapy in patients with alcohol use disorder). In addition, some guidelines have focused more broadly on evaluation of individuals who present with psychiatric symptoms or conditions.

Typically, the Committee on Practice Guidelines selects an illness/disorder that represents a significant public health problem (high prevalence and seriousness), is relevant to psychiatric practice, and for which there is a substantial body of evidence to support recommendations.

Identifying the Evidence

As noted above, guidelines must describe specific interventions and document the evidence that supports these recommendations. At the heart of the systematic review process is a detailed literature search, which is clearly delineated in each guideline, identifies keywords, and employs a MEDLINE search as well as specialized databases such as PsycINFO and the Cochrane Library.

The citations retrieved by the literature search are screened for inclusion in the systematic review based on the study design and relevance to the guideline topic. A rigorous approach is used such as that outlined by the AHRQ, which has many similarities to the methodology used by the Grading of Recommendations Assessment, Development and Evaluation (GRADE) group. Studies that meet inclusion criteria are assessed for aspects of study design, findings, and quality as shown in Table 7.3–2.

Synthesis of the findings of available research also follows a defined process as outlined in Table 7.3–3.

The overall strength of research evidence is not a measure of the size of the effect of the intervention but rather reflects the degree of confidence that additional studies will show similar conclusions. Factors that enter into this determination include the consistency of findings across studies, the directness of the effect on a specific health outcome, precision of the estimate of the effect, and the risk of bias in available studies.

Developing Guideline Recommendations

The drafting of practice guideline recommendations is a natural outgrowth of the review of the available evidence.

Beginning in 2014, these guideline recommendations are developed by the guideline writing group using an iterative Delphi process with discussion followed by blinded voting. If consensus is not reached, additional rounds of discussing and voting occur.

Based on the recommendations of the IOM, guideline statements are crafted in specific actionable terms that describe the circumstances or patient populations in which an intervention is to occur, the object of the action (if not the identified patient), and the individual carrying out the action (if not the psychiatrist or treating clinician). Whenever possible vague terms (e.g., moderate to severe symptoms) are explicitly defined or eliminated.

In addition, guideline statements are based upon the relative balance of benefits and harms of an intervention. Thus, a recommendation indicates confidence that benefits of an intervention clearly outweigh harms, whereas a suggestion indicates a greater degree of uncertainty, either that the balance of benefits and harms is more difficult to judge or that either the benefits or the harms are unclear.

Some guideline developers have attempted to limit guideline recommendations to those supported by randomized controlled trials (RCTs). However, other guideline developers recognize that additional forms of evidence are often needed in crafting guideline recommendations. For example, many aspects of clinical practice, including obtaining a patient history, have not been and cannot be studied with RCTs. Also, especially in psychiatry, RCTs and other trials often focus on pharmacotherapy or other somatic treatments and are limited in duration (often 6 to 12 weeks) because of funding issues. In addition, significant research challenges exist when studying some treatments, such as psychodynamic psychotherapy and some social therapies. For these reasons, expert clinical consensus is an essential component in the development of a guideline.

In an effort to make the expert consensus process more rigorous, APA has pioneered a “snowball” sampling methodology to identify clinical and research experts based on nomination of their peers. Nominated experts then receive a web-based survey with questions on the guideline topic. These expert survey results do not substitute for rigorous clinical trials, but answers to the expert survey are reviewed by the guideline writing group and can be particularly informative for situations in which clinical trials are not possible.

Format of APA Practice Guideline

Each APA practice guideline published between 1999 and 2014 followed a standardized format that included: (I) Executive Summary, (II) Formulation and Implementation of a Treatment Plan, (III) Specific Clinical Features Influencing the Treatment Plan, (IV) Disease Definition, Epidemiology, and Natural History, and (V) Review and Synthesis of Available Evidence. A discussion of Future Research Needs was also included.

The section of the guideline on formulation and implementation of the treatment plan discussed the use of specific somatic treatments and psychotherapies, but also described other important elements of psychiatric management that were essential for good care. Examples of such activities included: performing a diagnostic evaluation, evaluating the safety of the patient and others, evaluating the level of functional impairments, determining a treatment setting, establishing and maintaining a therapeutic alliance, monitoring the patient’s psychiatric status and safety, addressing comorbid disorders, providing education to patients and families, enhancing treatment adherence, and working with patients to address early signs of relapse.

Beginning in 2014, the format of the APA practice guidelines shifted to a different format, in part aimed at fulfilling the recommendations of the IOM. The new format is centered around specific guideline statements (e.g., recommendations, suggestions) accompanied by ratings of the strength of the recommendation and the strength of the supporting research evidence. A section on potential benefits and harms of the guideline statement is aligned with the GRADE methodology and describes the pluses and minuses of the intervention. This information is useful in understanding why the guideline statement was made and, along with the section on patient preferences, can be useful in shared decision making and, where relevant, informed consent. A section on implementation discusses approaches for integrating the recommendations or suggestions into routine care, including discussion of barriers to integration and ways to overcome them. This section also incorporates a discussion of circumstances in which guideline recommendations may not be appropriate, due to factors such as comorbid physical or psychiatric conditions. It also discusses relevant aspects of psychiatric management and ways in which patient values and preferences may shape recommended treatment approaches. To assure transparency of the guideline development process, the review of the supporting research evidence is included in the guideline in detail. Each guideline statement is also accompanied by a description of other organizations’ guideline recommendations on the same topic. This section is aimed at highlighting areas of consistency among guidelines but also to identify where different organizations may have drawn different conclusions about the evidence. An additional content area for each guideline statement relates to quality measurement. It discusses existing quality measures that are related to the guideline statement and, if existing quality measures do not exist or are insufficient, discusses whether and how to derive a quality measure from the recommendation. This section also discusses whether the guideline recommendation might be incorporated into electronic decision support or used as part of organizational quality initiatives to improve care.

In addition to information provided in relation to each guideline statement, the guideline includes descriptions of the development process, including the systematic review methodology. A section on the rationale of the guideline describes the guideline purpose and the epidemiology, morbidity/mortality, and other public health implications of the disorder or problem. Information on variations in clinical practice may also be discussed, if available and relevant. This section is intended to show clinicians, insurers, and policy makers why the guideline recommendations are important to patients, their families, health professionals, and society.

Review and Approval Process

The writing, review, and editing of a guideline is an iterative process. The number of drafts has evolved over the history of the practice guideline project and current processes focus on allowing a thorough review without untoward delays during which evidence becomes outdated. With the current process, the guideline draft is prepared by the guideline writing group and then reviewed by a large number of individuals, each of whom is asked to identify any potential conflict of interest. More specifically, the draft is distributed for review to at least 50 selected national and international expert reviewers, members of APA components and assembly, district branches, and allied organizations. Allied organizations include other medical specialties (e.g., neurology and family medicine), other mental health specialties (nursing, psychology, social work), and patient and family groups (e.g., National Alliance on Mental Illness [NAMI]). Reviewers are asked to make specific recommendations and, if possible, provide evidence to support their suggestions. Each suggestion is considered by the work group chair, the medical editor of the project, the project manager, and often the chair of the Committee on Practice Guidelines. The final draft is then prepared and is sent to the APA Assembly and the BOT for approval. Hence each guideline carries the authority of the Association, which aids in its acceptance and dissemination to the field.

Dissemination and Implementation Strategies

From the beginning of the project much attention has been directed to dissemination and implementation strategies. After approval, each guideline or a key portion of the guideline is published in the *American Journal of Psychiatry*. Many of the guidelines have also been published in a *Compendium of APA Guidelines* or, more recently, as free-standing publications. Some guidelines have also been formatted as six to eight panel pocket guides, following a model developed by the Veterans Administration, with the goal of improving the accessibility and usability of the guidelines in the day-to-day care of patients.

Each approved guideline is published in its entirety online on the APA website (https://www.psychiatry.org/psychiatrists/practice/clinical-practice-guidelines). Other resources that are available online at the APA site are clinician summaries, patient and family guides, continuing medical education courses, performance in practice (PIP) tools, and educational slide sets.

Updating of Guidelines

Because of the rapid growth of knowledge, keeping guidelines current is one of the major challenges facing this or any other guideline project. APA Practice Guidelines were scheduled for revision every 3 to 5 years. Because it takes about 2 years to develop a guideline, even if this schedule is followed (which has not consistently happened), guidelines may be 7 years old before a revision is published.

The change to a new format for guidelines was, in part, motivated by the need for continual updating of evidence and current recommendations. When guidelines encompassed all aspects of treatment for a given disorder, evidence and recommendations on one treatment might be outdated even when the remainder of the guideline was still current. When guidelines are based on more discrete topics, they can be updated independently of other topics that relate to the same disorder. APA is also exploring approaches to use informatics approaches to facilitate screening of new literature in order to support targeted updating of guidelines.

ADVANTAGES AND LIMITATIONS OF GUIDELINES

Table 7.3–4 identifies a number of potential advantages and limitations of guidelines.

Advantages of Guidelines

The most important benefit, and the major reason for developing and using guidelines, is to improve the quality of care received by patients. A growing body of literature, particularly related to cardiovascular disease, suggests that guideline adherence results in better outcomes. However, the available evidence is less clear in psychiatry, at least in part due to limited guideline adherence. Such studies are difficult to conduct especially when the guideline recommendations are multifaceted. Furthermore, rates of patient participation and adherence can confound interpretation of findings.

Table 7.3–4.
Advantages and Limitations of Guidelines

Advantages of Guidelines
Improve quality of care
Decrease variation in practice
Standardize and facilitate education of professionals
Education of patients and family
Facilitates patient involvement in decision making
Stimulate research
Encourage funding of research
Support reimbursement of evidence-based care
Reduce stigma

Limitations of Guidelines
Gaps in knowledge
Reality of comorbidity
Must change with new knowledge
Cookbook rather than art
Risk of reductionism
Stifle innovation
Concern about increased liability
Cost of development and implementation
Biased by funders of development
Difficult to implement

Geographic variations are well documented for rates of hospitalizations, procedures (such as hysterectomy or coronary artery bypass grafts), medication use, and other aspects of health care utilization. Within psychiatry, one study suggests that rates of death due to depression or schizophrenia also show significant geographic variation. Although this could be biased by differences in ascertainment, it may also reflect variations in care that are associated with variations in morbidity and mortality. Having nationally developed guidelines (if they are followed) can presumably decrease such variation and improve outcomes for patients.

Another major advantage of guidelines is their use in educational programs. Guidelines that include a clear and comprehensive description of the evidence and references are especially helpful. Interestingly, in many training programs it is the residents who push for increased use of the guidelines. Content related to the guidelines is also included in The Psychiatry Residents-in-Training Examination (PRITE) administered by the American College of Psychiatrists (ACP). Use of guidelines for educational purposes extends well beyond residency training into CME and MOC programs. The American Board of Psychiatry and Neurology (ABPN) has designated the APA guidelines as a major source for their MOC examinations and questions related to the guidelines are incorporated into the FOCUS self-assessment programs. Performance-in-practice modules are also available that are linked to guideline content.

Education of patients and families is also facilitated by the existence of guidelines. Many developers of guidelines also prepare a patient and family companion document that parallel the guideline but is written in a manner understandable for a lay audience. Such material also aids in involving the patient in the decision making, a major element in patient-centered care.

As guidelines are written, gaps in our evidence base become painfully clear. An important section in many guideline projects is to identify those issues that need to be further studied. This can provide direction to the field and also can be used to support requests for additional research funding.

To clinicians, decisions by third-party payers about what treatments are reimbursed frequently seem arbitrary or not driven by clinical reasoning. Practice guidelines can be used to identify those treatments that are supported by evidence and should be reimbursed and those treatments that are shown to be ineffective and should not be reimbursed. They can also delineate situations in which a number of options are appropriate and in which patient preferences and values should be taken into consideration and supported.

Guidelines are also valuable in demonstrating that mental illnesses are real and diagnosable, and that specific disorders and symptoms can be ameliorated with specific treatments. This is a crucial role for guidelines because stigma and its effects on patients, families, and treatment continue to be a major challenge. Over the past four decades, recognition of these realities has had a significant impact, directly and indirectly, on the funding of and access to treatment of mental illnesses.

Limitations of Guidelines

In terms of limitations to practice guidelines, gaps in the knowledge base make it challenging to write authoritative guidelines without overstating what the evidence supports. Poorly written guidelines can mislead physicians and patients and discredit the scientific underpinnings of our field.

Guidelines must be regularly revised as new knowledge becomes available. As the medical literature continues to grow at exponential rates and as the number of guidelines in a specialty area increases, this becomes a significant challenge for developers of guidelines. However, if guidelines are not updated regularly, they can be misleading to clinicians, patients, families, and policy makers.

Although treatment-related costs were highlighted by Dr. David Eddy as important considerations in practice guidelines, most guidelines do not incorporate cost-effectiveness data when developing guideline recommendations. Financial data to support such considerations is rarely available, and costs of a specific treatment or service can show wide variations. Translating costs to value (e.g., using quality adjusted life years) adds further complexities and sources of possible bias. Patients also vary in their available resources and in their cost-related preferences for treatment. Despite these challenges, the usefulness of practice guidelines is likely to be enhanced by some consideration of the costs and value of recommended care.

Guidelines that focus on a single illness/disorder are limited by the reality that many patients have multiple illnesses. In psychiatry, at least 50% of patients have more than one psychiatric diagnosis. Physical conditions are also common and can require modifications in treatment or monitoring. Hence, single-illness guidelines must address these realities. Ideally, more guidelines should be developed for comorbid conditions, but this is challenging, as there is limited evidence on the simultaneous treatment of comorbid conditions.

Care is also needed to reduce the number of inconsistent recommendations among guidelines written by different groups. Often these inconsistencies result from differences in the patient population of interest (e.g., primary care vs. specialty practices) or legitimate differences of opinion in interpreting the available evidence. Nevertheless, conflicting recommendations can be confusing for patients and clinicians alike. Transparency in the synthesis of evidence and rationale for recommendations can help to reduce some of these difficulties. Reviewing the recommendations of other organizations' guidelines as part of the guideline development process can also assist in clarifying or resolving discrepancies.

A frequent criticism of guidelines, especially when they were first being introduced, is that they encourage "cookbook" medicine and interfere with the practice of the "art" of medicine by being overly prescriptive. Well-written guidelines can avoid this pitfall by presenting the existing evidence and explicitly stating the role of the physician in using the recommendations to inform decision making about care.

A related issue is concern about guidelines reinforcing reductionism. Guidelines can potentially decrease the richness and breadth of assessment and treatment strategies, and developers of guidelines must be alert to this potential. Another concern is that new treatment approaches will be discouraged, and cutting-edge innovations will not be pursued. To address both of these concerns, guidelines may need to be more inclusive and less dogmatic, always describing the available evidence clearly and noting that other approaches may also constitute proper care for the disorder being considered.

Clinicians have been concerned that the presence of guidelines would lead to an increase in successful malpractice actions, as plaintiff attorneys could point out discrepancies between guideline recommendations and rendered care. Although evidence is limited, it appears that guidelines have been used by defendants as well as by plaintiffs to support their cases without significant increases in the number or severity of successful malpractice claims. To mitigate the possibility for misuse of guidelines in litigation, guideline writers should avoid being overly prescriptive unless the evidence is overwhelming and other choices are not reasonable. It must also be clearly stated that the recommendations are indeed guidelines, not standards of care. Instead, recommendations should be considered by the physician and decisions should be based on the needs of the individual patient, the available diagnostic and treatment options, and other circumstances.

Another limitation of guideline development is cost, which can be considerable. The federal government's Agency for Health Care Policy and Research developed 19 guidelines from 1992 to 1996, but the program was discontinued in part because of the considerable cost. As more scientific literature is available for review and as systematic review standards have become more rigorous, the costs of developing a guideline are even higher than in prior decades. While some of this cost can be offset by publication revenue from the guideline and related materials and income from educational programs, developing and disseminating guidelines is generally not a profitable undertaking. Some non-APA guidelines have been developed with the support of industry, especially pharmaceutical companies. This financial support raises a concern about the scientific integrity of the process and the independence of the recommendations.

Costs of implementation can also play a role in reducing guideline adoption with several studies noting that lack of administrative support and insufficient staff time were significant barriers. More recently, there has been increasing integration of guideline recommendations and related quality measures into electronic health records (EHRs), which can also add to implementation costs for software modification and staff time. In addition to these costs of guideline implementation, opportunity costs are often overlooked. If clinicians are focusing on delivering guideline-concordant care, they may overlook or lack the time to focus on other issues that would be of greater benefit to a particular individual.

Other difficulties in guideline implementation are also important to note. There are numerous studies indicating that often physicians do not use published guidelines. M.D. Cabana identified six primary barriers to guideline use: Lack of awareness, lack of familiarity, lack of agreement, lack of self-efficacy, lack of outcome expectancy, and inertia of previous practice. Some of these barriers can be surmounted through specific interventions. For example, some studies have shown that patient involvement in medical decisions increases the probability of receiving guideline concordant care. Other studies found that physician feedback or multifaceted educational programs including the use of opinion leaders improves the rate of physicians using guidelines. It has also been shown that use of guidelines may be enhanced by incorporating recommendations into EHRs. J.M. Grimshaw concluded that multifaceted interventions targeting different barriers to change in physician behavior are more likely to be effective than single interventions.

THE FUTURE OF PRACTICE GUIDELINES

There are now thousands of guidelines for all areas of medicine, which have been developed by professional associations, insurance companies, health care systems, and regional and national governments. The number of new guidelines will continue to increase dramatically over the next decade and will play an increasing role in the delivery of health care. With the integration of guidelines into EHRs, recommendations can be presented to clinicians at the point of service with more direct effects on clinical decisions. More research is needed on other tools and incentives to increase the use of guidelines. At the international level, greater efforts will be needed to explore the applicability of guidelines among different countries and to adjust recommendations on the basis of cultural differences, health care delivery systems, and available resources. If guidelines are well developed, truly evidence based, and appropriately flexible to meet the needs and wishes of individual patients, their use can significantly improve the quality of care for patients.

7.4 Neuropsychological Assessment of Adults

JOSEPH R. SADEK, PH.D., A.B.P.P.-C.N., OWEN GAASEDELEN, PH.D., REX M. SWANDA, PH.D., A.B.P.P.-C.N., AND KATHLEEN Y. HAALAND, PH.D., A.B.P.P.-C.N.

NEUROPSYCHOLOGICAL ASSESSMENT OF ADULTS

Clinical neuropsychology is a specialty in psychology that examines the relationship between behavior and brain functioning in the domains of cognitive, motor, sensory, and emotional functioning. The clinical neuropsychologist integrates the medical and psychosocial history with the reported complaints and the pattern of performance on neuropsychological procedures to determine whether results are consistent with a particular area of brain damage or a particular diagnosis. Although neurologic conditions are often the focus of referrals, the neuropsychological examination has a valuable place in diagnosing and identifying the pattern of behavioral and cognitive abilities that can be associated with various medical, psychological, and psychiatric diagnoses. Neuropsychology also plays a role in medicolegal and forensic applications, such as determination of decisional capacity, disability determination, and litigation over whether deficits are related to an injury.

WHO IS A CLINICAL NEUROPSYCHOLOGIST?

Clinical neuropsychology has well-established guidelines for standards of training and specialized practice in neuropsychology. In 1996, the field of neuropsychology was formally recognized as a distinct specialty in psychology by the American Psychological Association. The 1997 Houston Conference resulted in a policy statement that formally identified training experiences appropriate to developing a specialization in clinical neuropsychology. These training guidelines call for both specialized and generalized clinical training throughout a program of doctoral studies, followed by an internship and postdoctoral residency, leading to eligibility for specialty board certification through the American Board of Professional Psychology (ABPP), which is the parent board of the American Board of Clinical Neuropsychology (ABCN). Efforts are underway to update clinical neuropsychology training to apply competency-based standards put forth by the American Psychological Association.

RELATIONSHIP TO OTHER DISCIPLINES

The unique contributions of neuropsychology can be understood by examining its relationship to the closely allied disciplines of clinical psychology, behavioral neurology, and neuropsychiatry.

Clinical Psychology

Clinical neuropsychology is distinct from general clinical psychology by applying knowledge of brain–behavior relationships to assessing human behavior. Both areas rely on the psychometric foundations of reliability, validity, and normative standards to define behavioral symptoms and complaints objectively. Emotional factors are also the province of both. In evaluating cognition, the clinical psychologist focuses on issues involving general intellectual, academic, and vocational skills compared to clinical neuropsychology’s focus on neurologic factors. Clinical psychologists and clinical neuropsychologists are both involved in treatment, including psychotherapy and cognitive retraining to remediate deficits. Psychoeducation is also provided by both fields in a therapeutic context that discusses the relationship between symptoms and the assessment results and provides recommendations for patients, caregivers, and other health professionals.

Behavioral Neurology and Neuropsychiatry

The medical specialties of behavioral neurology and neuropsychiatry overlap considerably with clinical neuropsychology. However, the neuropsychologist's unique contribution to assessing cognitive deficits is based on a theoretical background shared with cognitive psychology and the neurosciences. It also uses rigorous, psychometrically based methods for developing and applying standardized tests with demographically appropriate normative data whenever possible. In contrast, the behavioral neurologist and neuropsychiatrist are more likely to utilize a mental status examination approach for identifying cognitive deficits. These clinicians typically rely on "internal norms," which are based upon the individual clinician's extensive experience with the examination procedures or pathognomonic signs (e.g., dysfluent speech or visual neglect). The behavioral neurologist is trained to diagnose a broad spectrum of neurologic disorders; the neuropsychiatrist's focus lies in diagnosing neurologic features of psychiatric patients though that focus has broadened in recent years. The neuropsychologist focuses on a formal assessment of various disorders' cognitive and behavioral manifestations that can produce cognitive and behavioral impairment in medical, surgical, neurologic, and psychiatric patients. Ideally, all three work together to provide complementary perspectives.

HISTORICAL INFLUENCES

Clinical neuropsychology has its roots in psychology, neurology, and psychiatry. The groundbreaking work of Broca and Wernicke in the 19th century first suggested that complex functions, such as speech and language comprehension, could be localized in particular areas in the left hemisphere. In 1909, K. Brodmann published a cytoarchitectonic map of the cerebral cortex (Fig. 7.4–1) based on different histologic patterns of cells in various parts of the cortex. Over the years, this representational map has proven valuable in identifying functional differences across distinctive cortical regions. Renewed interest in functional localization grew in the 1960s with Norman Geschwind's work in identifying how connections among different parts of the brain were most important in producing complex behavior. Arthur Benton's Iowa School developed a series of carefully constructed psychometric tests based on concepts originally identified by behavioral neurology to assess specific deficits relative to the normal population. At about the same time, Hans-Lukas Teuber defined the concept of "double dissociation," which is regarded as the strongest evidence for the localization of a particular function. This notion is based on observations of mutually exclusive brain–behavior relationships, such that damage affecting region 1 produces performance deficits in test 1 but not in test 2, while damage affecting region 2 produces performance deficits in test 2 but not in test 1. Aleksander Luria, the Russian neuropsychologist, also developed notions of functional localization but utilized a theoretical framework that associated component cognitive processes with complex skills and their neuroanatomical correlates. In the United States, Ralph Reitan applied the psychometric standards of North America to several instruments for the express purpose of assessing brain damage, resulting in the *Halstead–Reitan Neuropsychological Test Battery (HRNTB).* Current neuropsychological assessment practices attempt to use an efficient hypothesis testing approach, in which a core screening protocol is supplemented by procedures that assess specific areas of functioning. This approach is an outgrowth of the Boston or process approach to neuropsychological assessment combined with the more rigid and time-consuming HRNTB approach.

More recently, the development of increasingly sophisticated imaging techniques in the neurosciences (magnetic resonance imaging [MRI], computed tomography [CT], positron emission tomography [PET], functional MRI with connectivity analyses, and diffusion tensor imaging [DTI]) has brought dramatically enhanced capacity to integrate neuroimaging results with neuropsychological methods for measuring cognitive and emotional processing. Advances in neuroimaging have also influenced advances in cytoarchitectonic mapping. While Brodmann's map still functions as a standard reference for identifying cortical areas, an improved understanding of gray and white matter functional architecture leads to more detailed concepts (Amunts et al., 2020). The advances in brain mapping have not yet translated into similar advances in behavioral assessment.

NEUROANATOMICAL CORRELATES

The early history of neuropsychology was primarily driven by the goal of linking behavioral deficits to specific neuroanatomical areas of damage. Although this early assessment method helped validate neuropsychological tests commonly used today, the localizing function of neuropsychological assessment is now less critical since neuroimaging can easily visualize brain lesions. Increasing knowledge in neurosciences has also led to a more sophisticated view of brain–behavior relationships. Complex cognitive, perceptual, and motor activities are controlled by neural circuits and related small functional units rather than single structures within the brain. When evaluating patients with brain damage, it is necessary to understand these brain–behavior relationships and how disease states compromise their functioning. The following section will briefly review some basic concepts of brain–behavior relationships used routinely by the neuropsychologist to interpret neuropsychological results.

FIGURE 7.4–1. Brodmann's cytoarchitectonic mapping of the human brain. **A:** Lateral view. **B:** Medial view. (From Parent A. *Carpenter's Human Neuroanatomy*. 9th ed. Williams & Wilkins; 1996;882.)

Hemispheric Dominance and Intrahemispheric Localization

Many functions are mediated by both the right and left hemispheres. However, critical qualitative differences between the two hemispheres can be demonstrated after lateralized brain injury. Table 7.4–1 lists some cognitive skills linked to right-handed individuals' left or right hemisphere. Although language is the most obvious function controlled mainly by the left hemisphere, even among most left-handed individuals, the left hemisphere is also generally considered dominant for limb praxis (i.e., performing complex movements, such as brushing teeth). In contrast, the right hemisphere plays a more critical role in controlling visuospatial abilities and hemispatial attention, associated with the clinical presentations of constructional apraxia and neglect, respectively. Although lateralized deficits such as these are typically characterized by damage to the right or left hemisphere, it is essential to remember that preserved brain functions can also characterize the patient's performance. In other words, it is the remaining intact brain tissue that drives many behavioral responses following injury to the brain.

Table 7.4–1.
Selected Neuropsychological Deficits Associated with Left or Right Hemisphere Damage

Left Hemisphere	Right Hemisphere
Aphasia	Visuospatial deficits
Right–left disorientation	Impaired visual perception
Finger agnosia	Hemispatial neglect
Dysgraphia (aphasic)	Spatial memory
Dyscalculia (number alexia)	Dyscalculia (spatial)
Constructional apraxia (details)	Constructional apraxia (Gestalt)
Limb apraxia	Dressing apraxia
Verbal memory	Anosognosia

Language Disorders

LESIONS AND THE APHASIAS. Appreciation for the unique role of the "dominant" left hemisphere in controlling language in most right-handed individuals has been validated in many focal lesion, functional neuroimaging, and neurosurgery studies. Although it is rare for right-handed individuals to be right hemisphere dominant for language, it does occur in about 1% of cases. Hemispheric dominance for language in left-handed individuals is less predictable. About two-thirds of left-handed individuals are still left-hemisphere dominant for language, while about 20% each are right hemisphere dominant or bilaterally dominant.

Several classification systems have been developed over the years to describe various language breakdown patterns. A common method takes into account the presence or absence of three key features: (1) fluency, (2) auditory comprehension, and (3) repetition (i.e., intact ability to repeat verbally presented words or phrases). All of the following four types of aphasia have damage within some part of the middle cerebral artery's core distribution on the left hemisphere's lateral surface. Table 7.4–2 details the characteristics of *Broca's, Wernicke's, conduction, and global aphasia.* Each is characterized by different areas of brain damage within the middle cerebral artery territory and a different combination of nonfluent speech, impaired auditory comprehension, and repetition, or a combination of all three problems. In addition, more recent neuroimaging results in stroke patients show that the lesion locations specified in Table 7.4–2 may not be broad enough. For example, the full syndrome of *Broca aphasia,* including *agrammatism* (telegraphic speech), is found only in the presence of more extensive damage (i.e., suprasylvian area from Broca area to the posterior extent of the Sylvian fissure). Wernicke aphasia is associated with damage to the superior and middle temporal gyrus as well as the inferior frontal and parietal cortices, not just the superior temporal gyrus. The comprehension deficits seen with Wernicke aphasia result in impaired ability to comprehend their own language. Therefore, in contrast to patients with Broca aphasia who repeatedly try to correct their speech errors, the patient with *Wernicke aphasia* is typically not aware of their communication problems. This lack of insight is similar to the condition of *anosognosia,* in which patients fail to appreciate their own deficits, and presents a particularly frustrating condition for many family members and caregivers. *Conduction aphasia* produces more subtle, focal repetition deficits that negatively impact daily functioning somewhat less. *Global aphasia* is characterized by impairment in all three language functions due to damage to the core language areas on the lateral surface of the left hemisphere. Importantly, this system cannot neatly classify many aphasic patients because the pattern of deficits does not precisely fit clear, descriptive categories. Detailed language assessment of most aphasic patients typically demonstrates deficits in all three areas, although the degree of deficit among the three areas varies.

Table 7.4–2.
Aphasia Types with Traditional Lesion Loci

Aphasia	Primary Language Impairment	Lesion Location
Broca’s	Production	Posterior inferior frontal gyrus
Wernicke’s	Auditory Comprehension	Posterior superior and middle temporal gyrus
Conduction	Repetition	Arcuate fasciculus
Global	Production, auditory comprehension, and repetition	Broad area of the middle cerebral artery

NEURODEGENERATIVE LANGUAGE DISORDERS. Aphasia can be the initial presenting problem in variants of frontotemporal dementia (FTD), called *primary progressive aphasia*. Age of onset is typically in the sixth decade of life, and prevalence is less common than Alzheimer disease. Neuropsychological testing can help determine whether aphasia is the primary problem and can help determine whether it meets the criteria for the subsyndromes of language variant FTD. Subtypes of language variants are listed in Table 7.4–3.

Limb Apraxia. Limb apraxia and other cognitive-motor skills deficits are more commonly seen with left than right hemisphere damage. However, differences in the incidence of limb apraxia after left or right hemisphere damage is not as significant as with language, suggesting that left hemisphere dominance for disorders of complex movement is not as strong as that for language. Studies demonstrate that deficits in daily functioning are common with limb apraxia and that it negatively affects rehabilitation outcomes. Different types of limb apraxia have been associated with damage to different parts of the brain, especially in the left parietal, temporal and frontal regions. For instance, *ideomotor limb apraxia* is characterized by impaired spatiotemporal execution of complex movements, which results in orientation and timing errors, such as carving a turkey by moving the knife in a “jerky” up and down motion rather than smooth back and forth movements. These deficits have been associated with impairment of the “how” occipitoparietal circuit, which stores movement representations for familiar movements. *Ideational apraxia* might result in using the wrong object to perform a movement, such as attempting to use a toothbrush to eat, and sequencing errors, such as trying to light a candle before striking the match. Both types of problems have been associated with impaired semantic knowledge, characterized by an impaired appreciation of the object’s function and damage to the occipitotemporal lobe “what” system. Assessment of limb praxis can be challenging because aphasia and hemiparesis can influence the diagnosis, and there are relatively few standardized tests of limb apraxia, though a screening assessment that can be easily used at the bedside is now available.

Table 7.4–3.
Progressive Aphasia Types

Subtype	Clinical Features	Common Pathology and Location
Progressive nonfluent Aphasia	▸ Agrammatism ▸ Effortful, halting speech ▸ Impaired complex comprehension	Tau Left inferior frontal gyrus
Semantic dementia	▸ Impaired confrontation naming ▸ Impaired word comprehension ▸ Impaired object knowledge	TDP-43 Left anterior temporal lobe
Logopenic aphasia	▸ Impaired word finding ▸ Impaired repetition ▸ Phonologic paraphasias	AD Plaques and tangles Left temporoparietal junction

AD, Alzheimer disease; TDP-43, transactive response (TAR) DNA binding protein with Mr 43 kDa.

Visuospatial Disorders. Right hemisphere damage in right-handed individuals is frequently associated with deficits in visuospatial skills. Common assessment techniques include drawings and constructional or spatial assembly tasks. Although spatial problems are not recognized as frequently as language disorders, they can be highly significant from a functional standpoint. For example, they can be associated with getting lost even in familiar places and difficulty using a map to navigate unfamiliar places. Persons with hemispatial neglect (most frequently affecting the left hemispace) might have difficulty reading or reading an analog clock due to neglect of the left hemispace. In addition, persons with hemispatial neglect are at high risk for driving problems and, in extreme cases, might even leave food uneaten on the neglected side of a plate, for example. Spatial disorders might also produce difficulty dressing due to problems differentiating the garment's top, bottom, or left or right. Distinctive qualitative errors in constructing a complex geometric configuration can be seen with right or left hemisphere damage, though the deficits are typically more extreme after right hemisphere damage. For example, a patient with right parietal damage includes isolated design details while failing to convey the interrelationship of the details in the overall design configuration.

In contrast, a patient with left hemisphere damage tends to maintain the design's global framework or Gestalt but lose the details. See Figure 7.4–2 for an example from a common block design test. Therefore, many neuropsychologists emphasize that a neuropsychological understanding of the impairment depends not just on test scores but also on a qualitative description of the type of error. This often allows the impairment to be linked to a specific neuroanatomical region and enables a better understanding of the mechanisms of the deficit for rehabilitation purposes. This qualitative focus on the type of error is similar to the *pathognomonic* approach that behavioral neurologists often use.

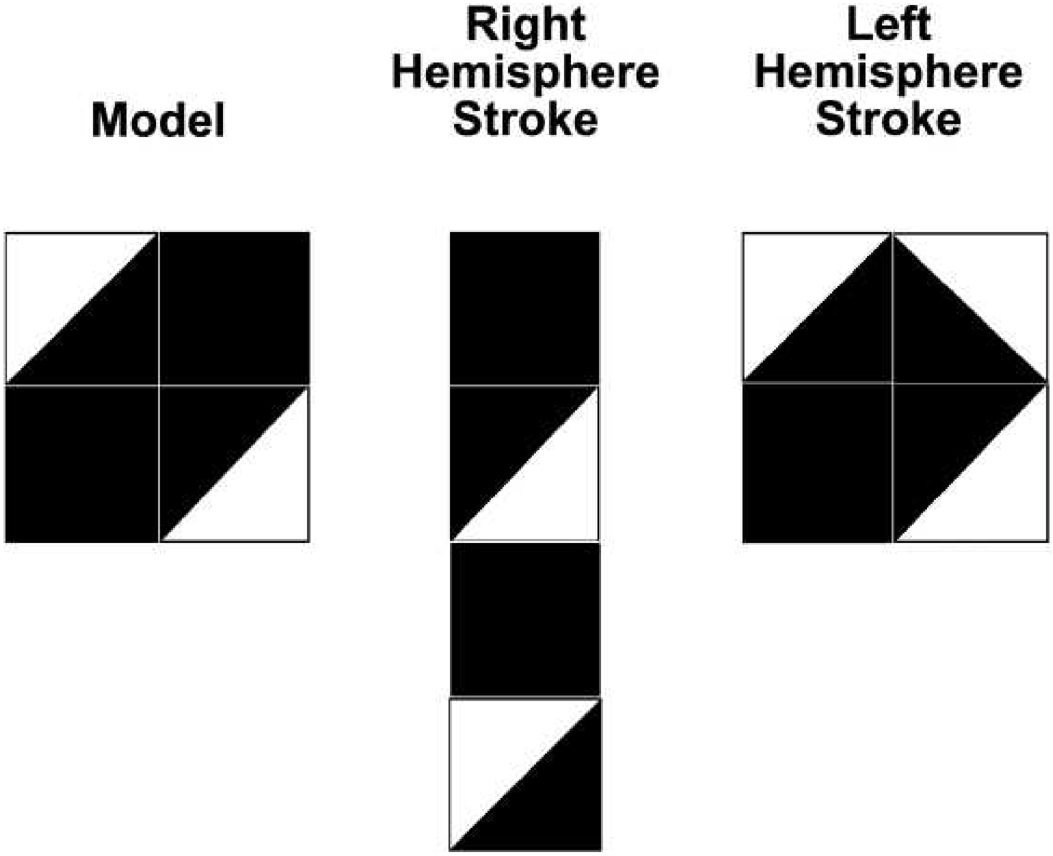

FIGURE 7.4–2. Block Design Examples.

NEGLECT. *Neglect syndromes* are characterized by failure to detect visual or tactile stimuli or move the limb in the contralateral hemispace. They are most commonly associated with right hemisphere damage in the parietal region, but damage to other areas within the cerebral cortex and subcortical areas can also produce this problem. Although neglect syndromes have a similar incidence and may co-occur with visual field cuts or somatosensory deficits, the neglect syndrome is distinct and not explained by any primary motor or sensory problems that may be present. Visual neglect can be assessed with line cancellation and line bisection tasks, in which the paper is placed at the patient's midline, and the patient is asked to either cross out all of the lines on the page or to bisect a single line. One of the most sensitive ways to assess visual neglect is with double simultaneous stimulation, which tests for the tendency to make errors in the contralesional hemispace when competing stimulation is in the ipsilesional hemispace. Neglect syndromes can have devastating functional effects on safety and the ability to live independently and should be considered standard in the evaluation process. For example, when working with a patient with visual neglect, the examiner should stand in the patient's nonneglected (usually right) hemispace to avoid being ignored. It is also essential to position a patient in an inpatient hospital setting so that the patient's "neglected" hemispace is oriented away from the door, thereby facilitating the patient's ability to pay attention to visitors entering the room.

Memory Disorders. Memory complaints constitute the most common referral to neuropsychology. Thorough neuropsychological examination of memory includes the verbal and/or spatial modality. Presentation formats systematically assess different aspects of information processing and storage that form the basis for human memory. Accumulated research indicates that specialized verbal and spatial memory material processing tends to be differentially mediated by the left and right hemispheres, respectively. In addition to interhemispheric differences in functional localization, specific memory problems can be associated with a breakdown at any stage in the information processing model of memory (Fig. 7.4–3). These stages include (1) registration of the material through *attention,* (2) initial processing and encoding of the material within *short-term memory,* (3) consolidation and storage of material in *long-term memory,* and (4) *retrieval* processes, in which material is accessed from long-term memory storage. A significant advantage of neuropsychological assessment is that these various types of memory problems can be specifically identified and described in the examination procedures. Once identified, the specific nature of the deficit can then have important implications for diagnosis, treatment, and prognosis.

FIGURE 7.4–3. Information Processing Model of Memory.

ENCODING. The initial encoding of new material can be influenced by various factors, including deficits in attention, language, and spatial processing abilities. It is usually measured by the immediate recall of newly learned information (e.g., narrative stories or designs) or by demonstrating the ability to learn new material that has been presented across multiple “learning trials” (e.g., word lists). Attention itself is a relatively fragile cognitive function that can be affected by many factors, including neurologically based disorders (e.g., traumatic brain injury [TBI], delirium) and psychiatric disorders (e.g., depression or anxiety, attention deficit disorder), so it is a crucial aspect of a proper memory assessment.

STORAGE AND RETRIEVAL. Storage of new information (retention) is assessed by determining the percent of the information recalled following a delay interval compared to what was initially recalled. Deficits in the delayed recall can be associated with impaired storage and retention of new information, or it can be due to impaired retrieval, in which case the material has been stored but not readily accessible. The best way of differentiating these problems is to examine *recognition memory,* in which a patient is typically asked to choose from a set of multiple-choice alternatives or discriminate target words from *false-positive* foils. Poor retrieval is the most likely problem if the patient demonstrates accurate recognition but poor recall. However, if recognition and recall are both impaired, the most likely problem is impaired encoding or storage of new information. This distinction is vital because different neuroanatomical systems subserve the functions of retrieval and storage. Impaired storage is more often associated with dysfunction of the medial temporal lobe–diencephalic systems, whereas impaired retrieval can be associated with various structures, especially the frontal lobes.

Executive Function. The prefrontal cortex and its interconnections with the rest of the brain play an important role in *executive functions,* which are essential for planning and organizing complex responses and self-monitoring, inhibiting inappropriate responses, and flexibly switching from one response strategy to another. Damage to the frontal lobes has also been associated with significant personality changes. This was historically exemplified by the famous 19th-century case of Phineas Gage, who became irresponsible, socially inappropriate, and unable to carry out plans after a tamping iron was blown through his frontal lobes. As conceptualized by Lezak, the executive functions include volition (i.e., formulation of a goal, motivation to achieve the goal, and awareness of one’s own ability to achieve the goal), planning, purposive action (response selection and initiation, maintenance, switching, and stopping), and execution, which involves self-monitoring and self-correction as well as control of the spatiotemporal aspects of the response. Although hemispheric differences in the control of executive functions by the frontal lobes have not been as well documented as language and spatial abilities in the parietal and temporal lobes, the Montreal Neuropsychology Group led by Brenda Milner has identified asymmetry in the control of verbal and design fluency.

Jeffrey Cummings proposed a model in which the prefrontal cortex and its interconnections are separated into the dorsolateral, orbitofrontal, and anterior cingulate divisions. In this model, various neurobehavioral functions are linked to corresponding neuroanatomical relationships between cortical and subcortical areas, especially the basal ganglia and thalamus. The *dorsolateral* prefrontal circuit is associated with higher cognitive functions, such as working memory, hypothesis generation, retrieval and initiation of unique words and designs, organization of information (e.g., clustering word lists based on semantic category), and development of alternating and sequential motor programs. The *orbitofrontal* syndrome is characterized by marked personality changes, such as instability, lability, and impulsivity. The *anterior cingulate* circuit is associated with impaired response initiation (i.e., akinetic mutism in the most extreme case) and response inhibition. These patients have difficulty inhibiting prepotent responses on “go–no go” tests and may be perceived by their families to be depressed, even though the patient might be content doing nothing. Yana Suchy has provided a more detailed description of these executive function deficits, including the Dysexecutive, Disorganized, Disinhibited/Initiation/Maintenance/Apathetic, and Socially Inappropriate Syndromes.

Motor Skills. The neuropsychological evaluation commonly includes formal motor skills tests, such as finger tapping speed, grip strength, and fine motor dexterity (e.g., grooved pegboard test). These tests, which have demonstrated validity and reliability, help assess lateralized motor impairment and determine the extent that motor deficits may confound the assessment of cognitive functions. Such motor deficits also have important implications for functioning in daily life and vocational planning.

PSYCHOMETRIC ISSUES

One of the strengths of neuropsychological assessment lies in the detailed quantitative record and normative standards for different areas of cognitive performance, which are the basis for conclusions. The normative database for any given test is significant to consider to ensure that deficits seen on individual test performances cannot be explained by demographic characteristics of the patient, such as age, education, language, or other social considerations. Of course, this approach is also dependent on the care used to develop and validate specific tests. The American Psychological Association has established ethical guidelines for psychological assessment that require tests to have acceptable levels of validity and reliability for the particular clinical application in which they are used. These guidelines serve as the basis for valid judgments about change over time, based on a given individual’s performance over successive examinations. This approach to standardization also ensures that test scores can be regarded as comparable even when administered by different examiners and in different settings. The American Academy of Clinical Neuropsychology has proposed uniform labeling of normed test performance to encourage more consistent descriptions of performances across providers and, therefore, more consumer-friendly reporting of results. Table 7.4–4 contains those labels and test descriptors.

Validity

Validity refers to a test's ability to measure what it purports to measure. Validity can be ascertained by (1) correlating scores from a particular test with other, well-established measures of the same skill, (2) relating test scores to diagnostic classifications or to measures of brain structure and function, or (3) relating test outcomes to aspects of everyday functions that are thought to be dependent on that skill. Historically, neuropsychological tests have been validated by examining their ability to differentiate brain-damaged patients from non–brain-damaged patients. More recently, they have been validated against neuroradiologic or neurosurgical data and diagnostic categories (e.g., patients with multiple sclerosis vs. medical controls). The movement to establish evidence that traditional neuropsychological tests can predict real-world outcomes has resulted in an empirical basis for inferring everyday functional problems from clinical neuropsychological test performance. Even validated measures directly assess everyday abilities, such as managing personal finances.

Table 7.4–4.
Uniform Labels of Neuropsychological Test Performance

Preamble: "In the Results section, the following phrases describe performance within the range of percentile ranks indicated in parentheses. Unless otherwise indicated, these descriptors are based on age-appropriate statistical norms and the aforementioned reservations. When adequate group norms are unavailable, more general terms reflecting behavioral observation and clinical judgment are used (e.g., "normal," "intact," "weak").

Label	Percentile Range
Exceptionally high	(98 or greater)
Above average	(91–97)
High average	(75–90)
Average	(25–74)
Low average	(9–24)
Below average	(2–8)
Exceptionally low	(<2)

Reliability

Reliability refers to the consistency of test scores. Tests are judged by (1) their internal consistency, or the extent to which all items appear to be measuring the same thing, (2) their ability to yield similar scores across multiple test occasions in normal individuals, and (3) the consistency in scores that are obtained when different people administer and score a test. Individual cognitive measures often have lower reliabilities than composite scores derived from several measures, and even within a particular ability domain, some measures exhibit higher reliabilities than others. For example, within the Wechsler Memory Scale-IV (WMS-IV), some individual tests of immediate and delayed memory have relatively low test–retest reliability (e.g., $r = 0.67$ and 0.64, for immediate and delayed visual reproduction, respectively), but the composite index scores for the Immediate Memory Index and Delayed Memory Index have higher test–retest stability ($r = 0.81$ and 0.82, respectively). This underscores the importance of using more than one test to measure each type of ability in a thorough neuropsychological evaluation. Therefore, it is crucial to consider reliability if only one test measure is used.

Predictive Utility

Predictive utility considers the sensitivity (true positives) and specificity (true negatives) of a test. A test that yields positive findings for most persons with the disease and negative outcomes for most persons without disease has high sensitivity and specificity. Published values for sensitivity and specificity are often based on ideal comparisons (e.g., clear cases of Alzheimer disease vs. carefully screened normal controls) and do not permit a clinician to estimate how useful a test will be in a general clinical population. It is essential to estimate in advance the predictive utility of particular tests for particular diagnoses because the predictive value of neuropsychological tests varies considerably for different diagnostic questions. For example, as discussed above in the section on *Neuroanatomical Correlates*, some particular neuropsychological deficits can be linked to injury in particular areas of the brain. However, many other neurologic diagnoses involve multiple brain systems that result in generalized impairment across a battery of tests. In testing for dementia, for example, neuropsychological test results are typically more sensitive than they are specific, so the interpretation must consider other medical and historical data to arrive at a more specific diagnosis. This underscores the importance of interpreting neuropsychological data in the context of the patient’s history and carefully examining the pattern of deficits and abilities with particular attention to demonstrating consistent deficits across different tests of a particular cognitive domain to reach greater accuracy.

Base Rates

Computation of positive and negative predictive values addresses practical questions: Given a positive test outcome, what is the probability of disease? Moreover, given a negative test outcome, what is the probability of not having a disease? Positive and negative predictive values are computed as the ratio of accurate positive findings to total positive outcomes and accurate negative findings to total negative outcomes, respectively. Predictive values are judged relative to estimated base rates of illness within the referral setting. For example, if the base rate of dementia among older adults referred for psychiatric assessment is

50%, then any test that purports to be sensitive to dementia must have greater than 50% predictive value to warrant its application.

Another aspect of the base rate is the frequency with which abnormal neuropsychological findings are obtained in normal individuals. This frequency is a significant consideration in neuropsychology, in which large batteries of multiple tests are usually administered. It is actually more typical than not for most “normal” persons to perform in the impaired range on some measures in an extensive battery of tests. For example, the 2004 manual of normative standards for the Halstead Reitan Battery points out how common it is for non–brain-damaged individuals without psychiatric problems to perform in the “impaired” range. Only 13.2% of healthy individuals completed a battery of 25 neuropsychological tests without any scores in the impaired range. In contrast, the same healthy group had a median value of three scores in the abnormal range, and more than 25% of the “normal” controls performed in the impaired range on six or more scores in the 25-score battery. Given these data, it would be very naïve to conclude that an individual is impaired by simply counting the number of neuropsychological test scores in the “impaired range.”

Instead, these data underscore how important it is to base the neuropsychological conclusions on a *pattern of performance* that is interpreted in the *context of the patient’s history.* The most substantial evidence of brain injury should typically be based on a pattern of impairment in domains consistent with empirical evidence for that condition, instead of impairment on isolated tasks scattered across different cognitive domains.

Selecting Appropriate Normative Data

Considerable research in recent years has been directed toward expanding the normative database for clinical neuropsychological tests concerning critical demographic factors. Normative data are now available for many cognitive measures across a broad *age* range. On average, persons in their early 70s score about a standard deviation lower than those in their 20s, especially on tasks that combine cognitive processing demands with speed requirements across a wide range of cognitive skills. So it is essential to compare a given older individual’s performance on neuropsychological tasks with that of age peers to ensure that any deficits demonstrated are not due to normal age-related changes. *Education* is also known to affect many aspects of cognitive performance strongly.

Gender differences are relatively small on most clinical neuropsychological tests, but there are a few types of tasks, such as motor speed and strength measures, where gender differences can be found.

Cultural factors and language background pose particular challenges in neuropsychological assessment concerning normative data selection. These factors are frequently addressed through clinical judgment and consultation with experts, but current best practices would encourage a neuropsychologist to seek the best possible cultural and language match between examiner and examinee. Although normative standards based on ethnicity have been developed for some groups, it is unlikely that appropriate normative standards will ever be developed for every specific ethnic and demographic group. Even then, ethnicity- and race-based norms may not be the appropriate basis for correction when the true causes of nonneurologic low test scores lie elsewhere, such as acculturation, literacy, native language, and issues related to economic status and geographical location. Much more research needs to be done to identify and quantify the full range of social determinants of test performance.

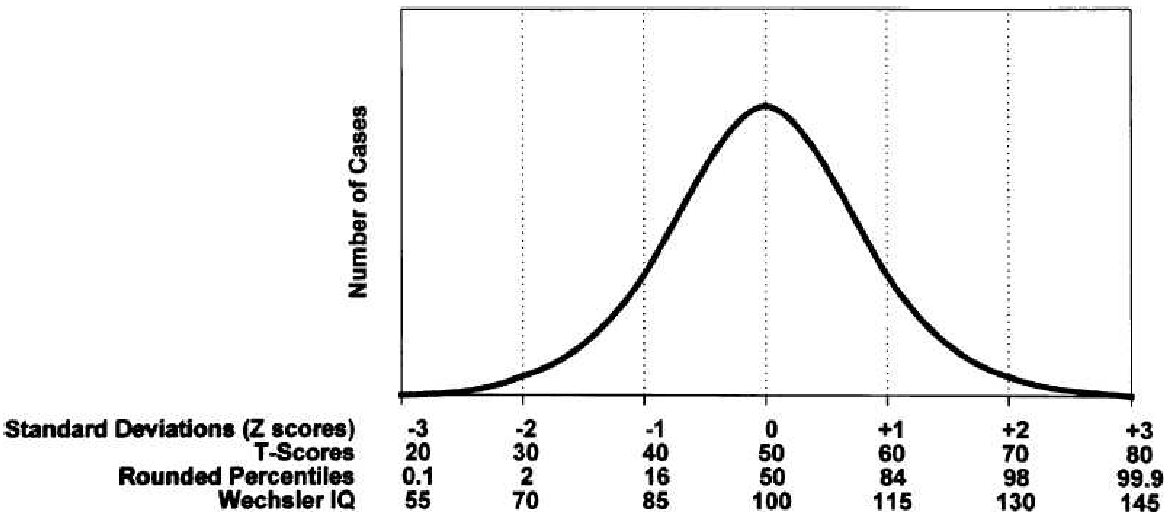

FIGURE 7.4–4. Normal Curve and Standardized Scores.

Estimates of Premorbid Functioning

The degree to which an individual's intellectual and cognitive performance is thought to be impaired is always based on the degree to which the performance differs from that individual's baseline or longstanding level of functioning, usually referred to as *premorbid functioning.* Because prior standardized baseline testing of cognitive abilities is not routinely available for most individuals, *premorbid functioning* is usually estimated. This functioning is based on educational and occupational history and performance on tests that are thought to be minimally affected by brain damage, such as tests of *crystallized intelligence* like vocabulary, general knowledge, or word-reading abilities. Impairment can then be defined as any statistically significant deviation from that individual's estimated level of premorbid ability. As illustrated in the normal *bell curve* that is shown in Figure 7.4–4, statistically significant results on any given set of tests would fall at least one standard deviation above or below the *mean* (or average) performance that is established for that individual, either in comparison to established normative standards or concerning his or her performance across the other tests.

If a 32-year-old Anglo man from the Midwest has only 4 years of education and has worked as a laborer, his premorbid level of functioning might be estimated to lie in the borderline to low average range. This represents the population that performs at least one standard deviation below average, and therefore most test scores for that individual would be expected to hover around that level. In the absence of pathognomonic signs of impairment, such as unilateral neglect or aphasia, it is typically more challenging to identify cognitive signs of cerebral dysfunction in such an individual unless a pattern of test scores falling at least two standard deviations below average emerges that is consistent with the medical history. This example demonstrates the importance of considering the broad context of demographic and cultural factors in the interpretation of neuropsychological evaluation.

Consideration of Diversity and Other Moderating Factors

As discussed above, performance on neuropsychological tests can be influenced by cultural, transient, or situational factors. In addition to gender, race, and ethnicity, notable aspects of individual culture and diversity that have been highlighted in the neuropsychological literature include education and literacy, degree of acculturation, primary language, socioeconomic status, communication style (e.g., direct vs. indirect), familiarity with the testing environment, the cultural conceptualization of intelligence, and immigration status. Practice guidelines from the American Academy of Clinical Neuropsychology call for neuropsychologists to be educated explicitly about cultural issues and have experience in administering and interpreting procedures that are relevant for the patient's cultural background, and refer to or consult with a more qualified examiner when needed. Ideally, patients should be referred to a neuropsychologist who shares a relevant cultural and linguistic background with the examinee and uses appropriate norms to reduce biased interpretation. However, even these steps might not account for more subtle sources of cultural bias. For example, an examinee, whose conceptualization of intelligence emphasizes careful attention to detail over speed, may interpret instructions for a measure of speed and attention very differently than an examinee who views intelligence as speed focused.

When diverse cultural factors appear to outweigh the assumptions on which normative comparisons are based, the neuropsychologist is expected to point out these limitations and acknowledge the conclusions' tentative nature. In such cases, direct observation techniques and intraindividual comparisons, combined with serial testing over time, may need to be prioritized over normative comparison. Careful consideration of cultural factors is also crucial in providing therapeutic and effective feedback. For example, individuals from specific cultural backgrounds may expect feedback that emphasizes the relationship between examiner and examinee, while others may desire greater focus on direct delivery of the findings from the evaluation and their real-life implications.

Transient factors, such as *alcohol and drug use,* can impair attention, memory, and cognitive processing speed, as can many *prescription medications,* especially in the older adults and brain injured. *Chronic pain* and the medications used to treat pain are also essential to consider. *Psychiatric disorders* such as mania, severe depression, or psychosis can undermine cognitive performance, rendering formal testing invalid in severe conditions or reducing scores below expected levels in milder cases. In short, all of these moderating factors combined with clinical observation and input from the patient and collaterals must be considered in interpreting the neuropsychological test results. An experienced neuropsychologist should also be expected to explicitly identify relevant factors that could be expected to undermine or contribute to lower than expected performance, such as impaired vision or hearing loss, acute illness, or recent significant stressors.

GENERAL REFERRAL ISSUES

Referring providers turn to neuropsychology for many reasons that include differential diagnosis, baseline measurement, treatment planning, and opinions regarding causality and decisional capacity. Because many referring providers have limited experience and knowledge of neuropsychology, the neuropsychologist needs to take an active role in refining the specific questions and providing practical information about the limitations of the consultation. An early conversation with a potential referring provider about such issues will foster realistic expectations and ensure that the neuropsychological evaluation is helpful in the patient's care. In general, it is not considered appropriate for a referring provider to request specific tests or procedures because the specific methods of neuropsychological assessment will necessarily reflect the patient's unique presentation of symptoms and complaints, history and development, the perspective of the neuropsychologist, and the referral question.

Level of Functioning

A common referral issue involves documentation of the level of functioning for various purposes, including assessment of functional change, vocational planning, capacity to live independently, manage personal health care, or make decisions, especially in the presence of diagnoses such as dementia, stroke, or head injury.

Differential Diagnosis

Like any other diagnostic procedure, the results of a neuropsychological examination must be interpreted in light of all available information, including the history and any associated medical factors that are documented or reported for the individual. Many neurologic and psychiatric disorders have similar clusters of symptoms in common, with complaints of concentration or memory problems being among the most frequently reported problems. For example, impaired attention and concentration are commonly found among patients who present with a history of mild closed head injury, psychiatric issues (e.g., depression, post-traumatic stress disorder [PTSD], or anxiety), or any of several types of neurologic disorders associated with subcortical involvement (e.g., Parkinson disease, multiple sclerosis, or human immunodeficiency virus [HIV]-related cognitive decline). A pattern of cognitive impairment across several critical areas of functioning does not necessarily provide a sufficient basis for a specific diagnostic conclusion. However, it must be integrated with the medical and relevant psychosocial factors to arrive at a specific differential diagnosis. The following discussion reflects some common clinical syndromes in which psychiatrists and neuropsychologists share an interest and may work together in assessing and treating patients.

Age- or Stress-Related Cognitive Change. Many middle-aged and older adults have concerns about everyday concentration and memory failures, and with heightened public awareness about conditions such as Alzheimer disease, an increasing number of these individuals seek evaluations for these concerns. A neuropsychological evaluation provides a detailed, objective picture of different aspects of memory and attention, which can be helpful in reassuring healthy persons about the integrity of their abilities. In addition, testing can reveal previously undetected mood or anxiety disorders that may contribute to cognitive concerns and provide a basis for suggestions about mnemonic strategies that can improve functioning in everyday life.

Mild Traumatic Brain Injury. TBI can be mild, moderate, or severe. These severity ratings are most commonly characterized by the duration of loss of consciousness or posttraumatic amnesia, as shown in the DSM-5 severity ratings in Table 7.4–5. In addition, most neuropsychological studies of the cognitive consequences associated with TBI have consistently found a strong relationship between the duration of loss of consciousness and cognitive recovery following TBI.

The vast majority of TBI cases referred for neuropsychological consultation involve mild TBI, from which an excellent cognitive recovery can be expected within days to weeks after injury. However, a significant proportion of persons who have suffered a mild TBI report subjective complaints that persist for many months after the injury, such as poor concentration and mood changes, fatigue, photosensitivity, balance problems, tinnitus, headache, or other forms of pain. This set of persistent subjective complaints is sometimes diagnosed as a postconcussional syndrome in the 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) or mild neurocognitive disorder in ICD-11. Several methodologically sound studies indicate that premorbid histories of psychological symptoms, including trauma and substance abuse, may be factors to consider. As noted in DSM-5, since co-occurring symptoms, such as depression, irritability, fatigue, headache, photosensitivity, sleep disturbance tend to resolve in the weeks following mild TBI, substantial subsequent deterioration in these areas should trigger consideration of additional diagnoses.

In many cases of mild TBI, there is no clear evidence of brain injury on MRI or other neuroradiologic tests. Therefore, neuropsychological testing often plays a crucial role in determining the extent of objective cognitive deficit and examining the possible role of psychological factors in perpetuating cognitive problems.

Table 7.4–5.
Traumatic Brain Injury Severity Criteria

Criteria	Mild TBI	Moderate TBI	Severe TBI
Structural imaging	Normal	Normal or abnormal	Normal or abnormal
Loss of consciousness (LOC)	0–30 minutes	>30 min and <24 hours	>24 hours
Alteration of consciousness/mental state (AOC)	a moment	up to 24 hours	>24 hours
Post-traumatic amnesia (PTA)	0–1 day	>1 and <7 days	>7 days
Glasgow Coma Scale (best available score in first 24 hours)	13–15	9–12	<9

Understanding the long-term consequences of TBI has improved significantly over the past 20 years. The work of Sureyya Dikmen and her colleagues has been particularly significant in demonstrating a *dose–response* relationship between the severity of the initial injury and the long-term cognitive consequences. For example, when loss of consciousness is behaviorally defined as “time to follow commands” on the Glasgow Coma Scale, those with relatively brief loss of consciousness are indistinguishable from healthy control subjects on cognitive functioning tests after about a year. The preponderance of evidence at this point indicates that persons who meet the criteria for mild TBI can be expected to recover fully in terms of cognitive functioning. However, when people with a history of mild TBI complain of enduring symptoms that exceed expectation, they should be carefully evaluated in order to identify any contributing psychological factors that could offer potential treatment strategies, such as symptoms of depression, anxiety, PTSD, substance abuse, or other psychiatric disorder. The issue of repeated mild TBIs causing a neurobehavioral disorder (chronic traumatic encephalopathy or CTE) has been proposed but not universally accepted.

The neuropsychologist should bear in mind that many patients with mild TBI are involved in litigation, complicating the neuropsychologist's ability to identify the causes for impairment. Although outright malingering is thought to be relatively infrequent and difficult to verify, the possibility of contributing psychological factors due to somatic symptom disorder, depression, PTSD, and substance use should be a significant consideration when potential legal settlements or disability benefits are in question. Several psychological models, such as "symptom misattribution" or "diagnosis threat," might explain some tendency to exaggerate symptoms based on the individual's expectations about how an individual with TBI might be expected to perform. The possibility of contributing psychological factors is significant to consider in the case of mild head injury, when subjective complaints may be disproportionate to the objectively reported circumstances of the injury.

Poststroke Syndromes. After the acute phase of recovery from stroke, patients may have residual deficits affecting cognitive skills or mood. A neuropsychological evaluation can help identify areas of strength, which can be used in planning additional rehabilitation and provide feedback on the functional implications of residual deficits for work or instrumental activities of daily living. Assessment of functional skills can also be helpful to a psychiatrist who is managing mood and behavioral symptoms or dealing with family caregivers.

Detecting Early Dementia. Conditions that warrant neuropsychological assessment for early detection and potential treatment include HIV-related cognitive deficits and normal pressure hydrocephalus. When concerns about a person's memory functioning are expressed by relatives instead of the patient, there is a higher probability of a neurologic basis for the functional problems since the loss of insight is a crucial feature of most neurodegenerative syndromes. Neuropsychological evaluation, combined with a good clinical history and other medical screening tests, can be highly effective in distinguishing early dementia from the mild changes in memory and executive functioning that can be seen with normal aging. A neuropsychological evaluation is beneficial in documenting the rate and pattern of cognitive deterioration over time and differentiating among different forms of dementia. An additional incentive for early diagnosis of dementia is that patients with early dementia may be candidates for memory-enhancing therapies (e.g., acetylcholinesterase inhibitors), and testing can provide an objective means of monitoring treatment efficacy.

Neuropsychological profiles have been used to identify patients who do not meet full criteria for Alzheimer disease but who report or demonstrate memory deficits with normal performance in other cognitive domains and with no or minimal functional complaints. This pattern, termed amnestic *mild cognitive impairment* (MCI), may represent prodromal Alzheimer disease or a transitional state in that such patients show a higher incidence of conversion to Alzheimer disease than individuals with no such cognitive impairment. MCI conversion rates to Alzheimer disease have been reported as 15% annually relative to conversion rates in those without cognitive deficits of about 2% annually. However, these conversion rates vary from 10% to 70% depending on the initial MCI diagnostic criteria used, which emphasizes the difficulties of operationally defining cognitive and functional decline. It is also important to note that the definition of MCI has been revised since its introduction to include nonmemory deficits, especially executive dysfunction, with the introduction of nonamnestic MCI and the potential of conversion to other types of dementia. However, the clinical implications of conversion to dementia are complex. For example, the diagnosis of Alzheimer disease should be addressed cautiously due to the possible negative emotional repercussions of such information, to the fact that not all MCI patients convert to Alzheimer disease, and that current medications produce only mild improvement even in patients diagnosed with Alzheimer disease. The MCI diagnosis should stimulate some consideration for providing affected patients and their families with information for future planning, such as financial management oversight and advanced directives. There is also some evidence that cognitive retraining may improve cognitive performance and subjective cognitive and emotional complaints. In the future, the combination of genetic information, neuroimaging and other biomarkers, and the behavioral evidence of neuropsychological assessment are likely to improve the ability to diagnose dementia at an earlier stage, which will be important as new treatments are developed.

Distinguishing Dementia and Depression. A substantial minority of patients with severe depression exhibit severe generalized impairment of cognitive functioning. In addition to problems with attention and slowing of thought and action, there may be significant forgetfulness and problems with reasoning. A neuropsychological evaluation can help identify a dementia syndrome associated with depression, historically known as pseudodementia, by examining the pattern of cognitive impairment. Mixed presentations are also common, in which symptoms of depression coexist with various forms of cognitive decline and exacerbate the effects of cognitive dysfunction beyond what would be expected from the neurologic impairment alone. Neuropsychological testing, in this case, can be beneficial by providing a baseline for measuring the effect of antidepressants or other therapy in alleviating cognitive and mood symptoms.

Presurgical Assessment

Neuropsychological evaluations before or after neurosurgery are used to assist surgical planning, assess prognosis, and evaluate outcomes. Neurosurgery for intractable seizures in patients with epilepsy usually involves pre- and postsurgical neuropsychological evaluations, in combination with the intracarotid sodium amobarbital procedure (ISAP), also referred to as the Wada test, or functional neuroimaging (also commonly conducted by neuropsychologists.). The ISAP has been considered the “gold standard” for language lateralization, and while testing utilizing fMRI is typically preferred as a less invasive alternative, the ISAP remains prioritized for examinees where atypical language representation is suggested, or fMRI is inconclusive. Tissue resection is planned to maximize seizure control and minimize cognitive morbidity. Medication-resistant Parkinson disease can be treated with deep brain stimulation (DBS), and neuropsychological assessment is conducted primarily to assess for risk of poor cognitive outcomes. Many studies have documented that cognitive impairment prior to DBS placement increases the risk for worse cognitive outcomes. Some brain tumor resection programs and epilepsy surgery programs employ neuropsychologists to conduct assessments during awake surgery to assist in protecting eloquent cortex. Finally, neuropsychologists also commonly perform evaluations prior to organ transplant to identify risks for poor outcomes, including cognitive impairment that may reduce adherence to medical treatments and health maintenance.

Change in Functioning Over Time

Because many neurologic diagnoses carry clear expectations regarding normal recovery rates and decline over time, it is frequently important to reexamine a given patient with a follow-up neuropsychological assessment to document any change after 6 months to a year. For example, neuropsychological evaluation could document the decline in independent functioning associated with a progressive dementia or identify improvement following a stroke or tumor resection. Follow-up examinations also provide an opportunity to objectively examine complaints of longstanding or worsening cognitive sequelae following mild head trauma, even though the current literature indicates that the most significant proportion of recovery of function is likely to occur over the initial 6 months to a year postinjury. Although continuing subtle signs of recovery can continue after that period, failure to improve following the injury—or to worsen of complaints—would suggest the possibility of contributing psychological factors or the existence of a preexisting or coexisting condition, such as substance abuse, dementia, or outright malingering.

Assessment of Decision-Making Capacity

Neuropsychologists are often asked to assist in determining an individual’s capacity to make decisions or manage personal affairs. A neuropsychological evaluation can be helpful in these cases by documenting areas of significant cognitive impairment and identifying areas of strength and well-preserved skills. However, legal opinions about decision-making capacity are seldom based on test scores alone but usually rely heavily on clinical interviews, collateral interviews with family or caregivers, and direct observations (e.g., in-home assessment) of everyday functioning. Appraisal of an individual’s level of insight and capacity to appreciate his or her own limitations is typically the most critical basis for an opinion about decisional capacity. Assessment of insight is based on the consistency between an individual's self-appraisal of their abilities and functioning, compared to objective evidence and observations of how the person functions independently and further informed by objective testing results. If there is a high agreement between the person's observed level of functioning and the person's self-appraisal of their own functioning, that person's level of insight is probably more intact than the person who rigidly insists that they are doing fine and defensively rejects assistance, despite objective evidence of self-neglect in the home, mounting financial calamity in the form of unpaid bills and a dangerous driving record. State statutes generally define standards for decision-making capacity, and, of course, the ultimate determination of competence rests with the presiding judge. However, the neuropsychologist or other health care professional can play a significant role in shaping the judge's ruling by providing evidence to the court in the form of a professional opinion supported by compelling behavioral data that has strong face validity.

As a general rule of thumb, consideration of decision-making capacity must be addressed in the narrowest possible sense to infringe as little as possible on the individual's freedom to represent their interests. The most common issues related to decisional capacity involve the areas of (1) financial and legal matters, (2) health care and medical treatment, and (3) ability to live independently. In addition, some capacity issues involve higher standards, such as the ability to drive and the ability to work or practice in a given profession (e.g., air traffic controller, pilot, surgeon, or financial advisor). In such cases, the neuropsychologist needs to rely on appropriate normative expectations for the type of activity and the patient's demographics. An excellent resource, entitled "Assessment of Older Adults With Diminished Capacity," is jointly published by the American Bar Association and the American Psychological Association, with three versions available online written for use by attorneys, judges, and health care professionals.

Forensic Evaluation

Neuropsychological evaluation of individuals in criminal or civil law matters requires specialized knowledge beyond general expertise in neuropsychology. Neuropsychologists are frequently called upon as experts in matters involving head injury in particular, especially in the case of mild head injury associated with a motor vehicle accident. As a distinct subspecialty, this area of practice requires integration of knowledge of statutes, laws, precedents, and legal procedures and expertise in identifying and describing the impact of an injury or event on cognitive, emotional, and behavioral functioning.

Ethical Considerations

Several ethical considerations are especially unique to the practice of neuropsychology. They include test and test data security, appropriate test measures, and confidentiality. Exposure of test materials to an examinee prior to the examination can render the results invalid and subsequently lead to invalid conclusions and possible harmful outcomes. As such, neuropsychologists must safeguard their testing materials. Since the raw test data (i.e., examinee responses) often contain copyrighted test materials, either in the examinee responses or in the test forms on which the responses are recorded, there are limited instances in which raw data should be released, usually only to another neuropsychologist.

In selecting tests, neuropsychologists must use tests that have sufficient evidence to support the test's intended use. Relatedly, neuropsychologists must use appropriate norms, and if significant differences exist between the examinee and the normative sample to which they are compared, neuropsychologists must account for these differences in their interpretation of the findings. With the increased utilization of assessment via videoconference and telephone, neuropsychologists must prioritize tests for which evidence exists for their utility in such a setting.

Neuropsychologists must explicitly discuss the limits of confidentiality with each examinee. Unlike psychotherapy, the results of neuropsychological evaluations are often shared with other professionals, so examinees should be informed of likely recipients of the final report and the degree of disclosure of sensitive information that may be necessary.

APPROACHES TO NEUROPSYCHOLOGICAL ASSESSMENT

The neuropsychological examination systematically assesses a broad range of cognitive functions and emotional status. Because deficits in cognitive performance can only be interpreted in comparison to a person's longstanding or *premorbid level of functioning,* overall intellectual abilities are typically examined to measure the current level of overall functioning and identify any changes in intellectual functioning. Psychological contributions to performance are also considered concerning personality and coping style, emotional lability, presence of thought disorder, developmental history, and significant past or current stressors. The expertise of the neuropsychologist lies in integrating findings obtained from many diverse sources, including the history, clinical presentation, and several dozen discrete performance scores that make up the neuropsychological data.

The specific neuropsychological assessment techniques used in a particular examination typically reflect the training and preferences of the neuropsychologist, as well as the referral issue. Historically, the actual practice and procedures of clinical neuropsychology developed in two general directions: the battery approach and the hypothesis testing approach. These are discussed next, and the reader can find more detailed descriptions among our references.

Battery Approach

The battery approach, exemplified by the HRNTB or the *Neuropsychological Assessment Battery* (NAB), grew directly out of the psychometric tradition in psychology. This approach typically includes a large variety of tests that measure most cognitive domains and sensory and motor skills. Traditionally, all parts of the test battery are administered regardless of the patient's presenting problem though the NAB has a screening examination that covers all appropriate domains. The battery approach has the advantage of identifying problems that the patient might not have mentioned and that the medical history may not necessarily predict. However, it has the disadvantage of being very time-consuming (i.e., 6- to 8-hour examination for the HRNTB).

Hypothesis Testing Approach

The qualitative hypothesis testing approach is historically best exemplified by the work of Luria and more recently developed as the *Boston Process Approach* by Edith Kaplan and her colleagues. It is characterized by a detailed evaluation of areas of functioning related to the patient's complaints and predicted areas of impairment, with relatively less emphasis on aspects of functioning that are less likely to be impaired. The hypothesis testing approach has been particularly helpful in illuminating the differential roles of the two hemispheres, as discussed above. This approach has the advantage of efficiently honing in on areas of impairment and producing a detailed description of the quantitative and qualitative deficits from a cognitive processing standpoint. However, it has the shortcoming of potentially overlooking unexpected areas of deficit.

Screening Approaches

Many practitioners have moved away from strict battery or hypothesis testing approaches since the 1990s and developed more flexible and efficient screening approaches. These changes in clinical practice are driven by economic factors that make it less practical to evaluate patients for long periods and the use of more efficient, empirically based clinical practice standards that draw on a widening array of well-normed clinical instruments. In this model, the neuropsychologist utilizes a core set of screening procedures as a first step in determining whether a diagnosis can be made with less information or whether additional testing is necessary to identify more subtle problems. Therefore, a screening protocol that efficiently assesses the significant areas of neuropsychological functioning may or may not be followed by more detailed testing in selected areas that might help to understand better the reasons for the deficits demonstrated on the screening evaluation. The *Repeatable Battery for the Assessment of Neuropsychological Status* (RBANS) and the NAB provide examples of standardized screening approaches that have the advantage of uniform normative reference groups. However, many clinicians routinely use tests drawn from many sources.

Mental Status Examinations

In some cases, usually involving very acute or severe cognitive impairment, it is simply not feasible to administer extensive cognitive examination procedures. Instead, the neuropsychologist might rely on bedside mental status examinations or very brief cognitive screening procedures to address referral issues. However, research has shown that, even with brief screening procedures, the systematic use of a structured examination format can significantly increase the accuracy of detecting cognitive impairment. Therefore, several mental status screening procedures are commonly used by various health care providers in general medical and geriatric settings to provide an initial assessment of mental status. Along with a careful history, these screening procedures can serve as an indicator for more precise neuropsychological evaluation, as well as a quick baseline against which to monitor changes in cognitive functioning.

One of the most widely used screening instruments for documenting gross changes in mental status is the Mini-Mental State Examination (MMSE), although its use has declined since it is no longer in the public domain. However, two newer mental status screening approaches that are publicly available may be even more sensitive to cognitive deficits than the MMSE. Both the Montreal Cognitive Assessment (MoCA) and the St. Louis University Mental Status Examination (SLUMS) include measures of verbal fluency and clock drawing that can reflect executive functioning. The MoCA has the additional advantage of assessing abstraction ability, while the SLUMS includes items that assess story recall, mental calculations, and size differentiation. Like the MMSE, all of these mental status screening tools are likely to underestimate the degree of cognitive deficits in well-educated older persons with early Alzheimer disease or in younger adults with focal brain injury but more likely to overestimate the presence of cognitive deficits in persons with little formal education. Therefore, cut-off scores should be adjusted for age and education before concluding that impairment is present. Although mental status examinations can be beneficial in screening for gross signs of cognitive impairment, they do not provide a sufficient foundation for diagnosing specific etiologies of cognitive impairment, and they are not interchangeable with a more detailed neuropsychological evaluation.

Teleneuropsychology

The COVID-19 pandemic forced a seldom-used approach (i.e., telephonic and videoconference evaluations) into the mainstream. Fortunately, it will result in a new and permanent addition to a widespread practice that will benefit patients in remote locations who may not otherwise have access to neuropsychological services. The practice of teleneuropsychology, of course, limits the kinds of tests that can be administered since the medium of telephone or video telehealth introduces variables that can reduce the reliability or validity of tests that were designed for in-person use (e.g., the patient’s video device may display stimuli differently enough from the original that the test becomes invalid). When the telehealth technology falters or fails, the interruption can invalidate tests, especially when the responses involve timing. In addition, there can be a complete loss of connection, and the evaluation may have to be conducted in person. The test environment cannot be controlled with teleneuropsychology, where the examinee is usually in a location separate from the examiner. This dilemma is particularly problematic for forensic evaluations, where threats to validity are even more closely scrutinized. As of the writing of this chapter, there is limited literature on the reliability and validity of teleneuropsychology, but the rapid increase of its use will undoubtedly result in more empirical evidence to support its use. It likely will result in the development and validation of teleneuropsychology tests.

DOMAINS OF FORMAL NEUROPSYCHOLOGICAL ASSESSMENT

The past decade has seen a virtual explosion in the growth of more sophisticated and better-standardized tests and procedures for neuropsychological evaluation. A comprehensive listing of tests and techniques is beyond the scope of this chapter, but standard works that provide excellent reviews of current techniques are found in texts referenced in this chapter. A list of some examples of common neuropsychological tests and techniques is provided in Table 7.4–6.

Table 7.4–6.
Selected Tests of Neuropsychological Functioning

Area of Function	Comment
Intellectual Functioning	
Wechsler Intelligence Scales	Age-stratified normative references; appropriate for adults up to age 89, adolescents, and young children
Test of premorbid functioning	Estimates predisease intellectual abilities based on a test of word reading and demographic factors. Conormed with the WAIS-IV to yield regression-based IQ and other ability estimates
Attention and Concentration	
Digit span	Auditory-verbal measure of a simple span of attention (*Digits Forward)* and cognitive manipulation of increasingly longer strings of digits (*Digits Backward, Sequencing*)
Digit Vigilance Test	Assesses both speed and accuracy of attention using an array of rows of randomized numbers in which a specific digit must be crossed out
Paced Auditory Serial Addition Test (PASAT)	Requires double tracking to add pairs of digits at increasing rates; particularly sensitive to subtle simultaneous processing deficits, especially in head injury
Memory	
Wechsler Memory Scale-IV	Comprehensive set of subtests measuring attention and encoding, retrieval, and recognition of various types of verbal and visual material with both immediate recall and delayed retention; Excellent age-stratified normative comparisons for adults up to age 90 with intellectual data for direct comparison
California Verbal Learning Test	Documents encoding, recognition, and both immediate and 30-minute recall; affords examination of possible learning strategies as well as susceptibility to semantic interference with alternate and short forms available

Fuld Object Memory Evaluation	Selective reminding format requires the patient to identify objects tactually, then assesses the consistency of retrieval and storage as well as ability to benefit from cues; Normative reference group is designed for use with older individuals
Hopkins Verbal Learning Test-Revised	A brief list learning paradigm in which a 12-item word list is recalled across 3 learning trials. Delayed recall after 15 minutes followed by a recognition discrimination trial help isolate memory problems related to encoding, retention, and retrieval
Brief Visuospatial Memory Test-Revised	Serial learning approach used to assess recall and recognition memory for an array of 6 geometric figures; 6 alternate forms
Language	
Boston Diagnostic Aphasia Examination	Comprehensive assessment of expressive and receptive language functions
Boston Naming Test-Revised	Documents word-finding difficulty in a visual confrontation format
Verbal fluency	Measures ability to fluently generate words within semantic categories (e.g., animals) or phonetic categories (e.g., words beginning with “S”)
Token test	Systematically assesses comprehension of complex commands using standard token stimuli that vary in size, shape, and color
Visuospatial–Constructional	
Judgment of line orientation	Ability to judge angles of lines on a page presented in a match-to-sample format
Facial recognition	Assesses matching and discrimination of unfamiliar faces
Clock drawing	Useful screening technique is sensitive to organization and planning as well as constructional ability

Rey–Osterreith Complex Figure Test	Ability to draw and later recall a complex geometric configuration; sensitive visual memory as well as executive deficits in the development of strategies and planning
Motor	
Finger tapping	Standard measure of simple motor speed; particularly useful for documenting lateralized motor impairment
Grooved pegboard	Ability to rapidly place notched pegs in slotted holes; measures fine finger dexterity as well as eye–hand coordination
Grip strength	Standard measure of lateralizing differences in strength
Executive Functions	
Wisconsin Card Sorting Test	Measure of problem-solving efficiency is particularly sensitive to executive deficits of perseveration and impaired ability to generate alternative strategies in response to feedback flexibly
Category Test	This measure of problem-solving ability also examines the ability to benefit from feedback while flexibly generating alternative response strategies; regarded as one of the most sensitive measures of general brain dysfunction in the Halstead–Reitan battery
Trail-Making Test	Requires rapid and efficient integration of attention, visual scanning, and cognitive sequencing
Delis–Kaplan Executive Function System (D-KEFS)	Battery of measures that are sensitive to executive functions
Comprehensive and Screening Batteries	
Neuropsychological Assessment Battery	The NAB is a comprehensive and conormed assessment that offers the combined strengths of both a flexible and fixed battery to allow

	clinicians to focus on specific areas of concern, with 5 domains and 33 tests
Halstead–Reitan Neuropsychological Test Battery (HRNTB)	A compilation of neuropsychological tests designed to evaluate functioning, with versions for children and adults. Demographically corrected norms for an expanded version are available for adults
Repeatable Battery for the assessment of Neuropsychological Status	Brief battery with five domains and two versions designed for repeat testing. Norms for ages 12 to 89, though especially useful in the older adults
Psychological Factors	
Beck Depression Inventory	Brief (5–10 minutes) self-report measure that is sensitive to symptoms of depression. Best for screening depression in adults up to late middle-age, who can be expected to report symptoms frankly. Available in standard (21 four-choice items) or short (13-item) form
Geriatric Depression Scale	30-item self-report screen for symptoms of depression. The yes–no format is less cognitively demanding than other scales
Minnesota Multiphasic Personality Inventory (MMPI)-2-RF and MMPI-3	This self-report instrument is highly useful for documenting a wide range of psychological symptoms and statistically determined validity indicators and information about an individual’s response style. The MMPI-2-RF was a psychometric revision of the previous instrument, while the MMPI-3 was recently published with new norms and new and updated items
Personality Assessment Inventory (PAI)	Self-report instrument that is useful for psychological treatment planning, implementation, and evaluation has empirical support for use in forensic settings. In addition,

	fourth grade reading-level questions make it somewhat easier to complete than the MMPI
Performance Validity	
Test of Memory Malingering (TOMM)	Effectively identifies persons who tend to exaggerate impairment using a forced-choice recognition procedure based on 50 line drawings of common objects
Green Word Memory Test	Identification of poor effort on memory testing, indices that distinguish feigned vs. genuine memory impairment

Interview

The clinical interview provides the single best opportunity to identify the patient’s concerns and questions, elicit a direct description of current complaints from the patient, and understand the context of the patient’s history and current circumstances. Although the patient typically serves as the primary information source, it is vital to seek corroborating information for the patient’s account from an interview with caregivers or family members and thoroughly review relevant records, such as medical and mental health treatment, educational, and employment experiences.

Intellectual Functioning

Assessment of intellectual functioning serves as the cornerstone of the neuropsychological examination. The Wechsler Intelligence Scales have represented the traditional “gold standard” in intellectual assessment for many years, based on carefully developed normative standards. The scope and variety of subtests on which the summary intelligence quotient (IQ) values are based also provide valuable benchmarks against which to compare performance on other tests of specific abilities. The latest revision of this instrument, the *Wechsler Adult Intelligence Scale IV* (WAIS-IV), released in 2008, offers the additional advantage of greatly extended age norms (ages 16 to 89) directly related to normative WMS-IV performances. The Wechsler Intelligence Scales utilize a broad set of complex verbal and visuospatial tasks that can be summarized as Full Scale IQ, with composite scores in the domains of Verbal Comprehension, Perceptual Reasoning, Working Memory, and Processing Speed. In the context of a neuropsychological examination, the patient’s performance across the procedures provides a reasonable basis for estimating an individual’s level of premorbid abilities and the current level of intellectual functioning. Most neuropsychologists recognize that the summary Full Scale IQ provides only a ballpark range for characterizing an individual’s general level of functioning. It is usually more appropriate and meaningful to characterize an individual’s level and consistency of functioning (e.g., borderline, low average, average, high average, or superior) across the various domains represented by the composite scores rather than focusing on a specific IQ value.

Careful examination of the individual’s performance across the various subtests within each composite area can provide information regarding the patient’s pattern of strengths and weaknesses and the degree to which these performance characteristics are consistent with the history and performance on other aspects of the neuropsychological examination. For example, tests that measure longstanding, accumulated knowledge, such as vocabulary or fund of general information, provide a basis for estimating an individual’s longstanding (or premorbid) level of intellectual abilities, which in turn can help to gauge the degree to which an individual may have deteriorated.

Attention and Information Processing

Attention underlies performance in virtually all other areas of functioning and should always be considered a potential contributor to impairment on any tests requiring sustained concentration and vigilance or rapid integration of new information. In a broad-based neuropsychological examination, measures of attention and concentration provide a helpful basis for “previewing” the individual’s ability to comprehend, process information, and otherwise engage in the assessment process. *For example, digit span* requires patients to repeat increasingly longer strings of digits as a way of assessing the ability to process relatively simple information. In contrast, *digit span backward* reflects more complex simultaneous processing and cognitive manipulation demands or working memory. More demanding attention and information processing measures have also been developed that are highly sensitive to subtle deficits in rapid simultaneous processing. For example, the *Paced Auditory Serial Addition Test* (PASAT) requires patients to successively sum pairs of numbers at increasingly faster rates of presentation, adding each new digit to the immediately preceding digit in a highly demanding test of working memory. Other procedures for assessing attention and sustained concentration can be found in pencil and paper measures of digit, letter, or symbol cancellation and various versions of computer-assisted measures of attention and vigilance.

Memory

Complaints of memory problems constitute one of the most common reasons for referral to neuropsychology. As described above, the neuropsychologist utilizes an information processing approach to assess memory problems that might involve difficulty with encoding, retrieval, or storage of new information. The (*WMS-IV* is the latest revision of a widely used battery of subtests that utilizes several measures of attention, memory, and new learning ability. The original version, which David Wechsler developed in 1945, was extremely limited and did not include delayed recall. A revised version of the battery was published in 1987, which added delayed memory and included five summary indices: Verbal and Visual Memory, General Memory, Attention/Concentration, and Delayed Memory. The current version, published in 2009 (WMS-IV), has a modified index structure that assesses auditory memory using immediate and delayed recall for a story narrative (Logical Memory I and II) and a set of word pairs (Verbal Paired Associates I and II). Visual Memory is assessed using immediate and delayed memory for the visual detail and spatial location of a set of Designs and Visual Reproduction of designs to make sure that deficits are not due to visuospatial deficits independent of memory. Other Index domains of the WMS-IV include visual working memory, immediate memory, and delayed memory. The WMS-IV offers additional advantages by extending the normative comparisons to age 90 and adding a set of mental status screening procedures (Brief Cognitive Status Exam) for older adults.

A well-standardized example of a verbal list learning technique is the *California Verbal Learning Test 3* (CVLT-3), published in 2017. This procedure employs 5 learning trials of a 16-item word list, which comprises 4 exemplars from each of 4 semantic categories. Aside from measuring several aspects of learning and memory, the CVLT-3 also yields rich qualitative data about the patient’s use of higher-order conceptual strategies and the efficiency of verbal learning. Proactive interference is examined using a single free recall trial of a second list of words. Free and cued recall of the original list after both short and long delays, as well as recognition and forced-choice trials, further examine memory processes of storage, retention, and retrieval. Published norms for this instrument extend from ages 16 to 89 for males and females with education, region, ethnicity, and age norms. This revised task also offers the advantages of an alternative form and a nine-item short form. Because administration time for the standard form typically requires 15 to 25 minutes (not counting a 20-minute delay interval), the short form can be beneficial for examining more severely impaired individuals or individuals with limited formal education. The Rey Auditory Verbal Learning Test (RAVLT) is similar to the CVLT except that the words are not semantically related and the normative standards are not as extensive.

The *Hopkins Verbal Learning Test-Revised* (HVLT-R) is another helpful list-learning task for older or more impaired individuals in which a 12-item word list is presented in 3 learning trials, with follow-up measures of delayed recall after a 15-minute delay interval and a recognition discrimination trial. Its other significant advantage over the CVLT and RAVLT is that there are multiple parallel forms.

Several procedures have been standardized over the years for assessing memory for visual material. These include the *WMS-IV Visual Reproduction*, *Rey–Osterreith Complex Figure Test,* and further discussed as a visual-spatial assessment technique below. In addition, the *Brief Visuospatial Memory Test-Revised* offers six alternate forms and uses a three-trial serial learning approach to assess recall and recognition memory for an array of six geometric figures presented in a 2 × 3 array on a single page.

Language

Assessment of language examines both expressive abilities and comprehension. However, most neuropsychologists screen for language impairment rather than administer an extensive formal language assessment battery, such as the *Boston Diagnostic Aphasia Examination* (BDAE) or the *Western Aphasia Battery* (WAB). Measures of verbal fluency commonly assess expressive language. Specific procedures and normative data for several versions of verbal fluency measures can be found in the *NAB* and the Heaton norms manual. Visual confrontation naming is another commonly assessed aspect of language. The *Boston Naming Test-Revised,* published in 2001, provides a standard 60-item measure, and the NAB offers a shorter alternative measure of visual confrontation naming ability. Standardized comprehension evaluation often employs procedures that systematically assess one-, two-, and three-step commands in a format, such as the *Token Test.* At the same time, the Complex Ideational Material subtest of the *Boston Diagnostic Aphasia Examination* examines an individual's ability to comprehend more complex narrative material through responses to a series of yes–no questions.

Visuospatial Functions

Complex visuospatial abilities can be assessed through an extensive array of procedures found in various batteries with well-developed normative data and stand-alone tests that vary in the quality of the norms. The perceptual reasoning measures of the WAIS-IV include block design, visual puzzles, and matrix reasoning, all of which can help provide an understanding of an individual's ability to perform on tests of visual constructional ability and abstract concept formation. The NAB offers several standardized assessment procedures. It has a spatial module that includes visual discrimination based on a match-to-target paradigm. A design construction task also uses a set of seven geometrically shaped pieces to copy a two-dimensional design and a figure drawing task with immediate recall of a geometric figure. The battery also includes a map reading task that measures visual–spatial skill, spatial/directional orientation, right–left orientation, and visual scanning. Arthur Benton's laboratory developed a set of widely used stand-alone measures, such as *Facial Recognition, Visual Form Discrimination,* and *Judgment of Line Orientation.* Other measures of visual constructional ability examine the person's ability to draw spatial designs or assemble two- or three-dimensional figures (see examples in Fig. 7.4–2). In addition to the significant visuospatial component, these tasks reflect executive planning and organizational abilities contributions. More impaired individuals can be asked to copy simple geometric forms, such as a Greek cross or intersecting pentagons, to examine visuospatial abilities less influenced by planning and organization.

The widely used technique of *clock drawing* provides a surprisingly sensitive measure of planning and organization, especially for older individuals at risk for dementia. While problems involving poor organization, perseveration, and possible neglect may be obvious, more subtle difficulties can also be detected, especially when a patient's performance is evaluated based on premorbid expectations. Like most neuropsychological assessment techniques, it is essential to use even this relatively simple procedure in a standard manner. Most neuropsychologists use the same set of instructions each time, offering the patient a single sheet of unlined paper and saying, "Now I would like you to draw a clock. Put all the numbers on the clock, and set the time to 10 after 11." It is best to encourage the patient to use the whole page and draw a relatively large clock so that subtle evidence of neglect or executive deficits in organization and planning are more pronounced. Although the rich qualitative information that can be gleaned from this task may not be sufficient to stand alone for diagnostic purposes, this measure provides a valuable screening technique—especially for older or more seriously impaired individuals—and can serve as a basis for deciding whether to refer the patient for more detailed neuropsychological examination.

The *Rey–Osterreith Complex Figure Test* is a more demanding constructional task that requires the individual to copy a highly complex geometric configuration and then draw the figure from memory. Important qualitative information about the examinee's problem-solving approach can be extracted by carefully monitoring and documenting the examinee's strategy to draw the figure. It should be noted that apparent visual–spatial constructional difficulties can also be observed in the presence of frontal executive types of problems due to impaired organization and planning or poor self-monitoring.

Sensory and Motor Functions

Double simultaneous stimulation in the visual, tactile, and auditory modalities is a standard component of the HRNTB. It can help assess the integrity of essential sensory functions and neglect if deficits are present on one side only on the simultaneous bilateral trials and not when stimulation is unilateral. *For example, grip strength* and rapid *finger tapping* are commonly used measures of motor strength and speed-sensitive to lateralized brain dysfunction. A related measure, the *grooved pegboard,* assesses the individual's ability to integrate fine finger dexterity, motor speed, and eye–hand coordination efficiently but may be bilaterally impaired following unilateral brain injury due to its high demands for cognitive integration.

Executive Functions

One of the most critical aspects of the neuropsychological examination lies in the assessment of *executive* functions, which play a vital role in the planning and initiation of independent activities, self-monitoring of performance, inhibition of inappropriate responses, switching between tasks, and planning and control of complex motor and problem-solving responses. Although the prefrontal lobes have long been regarded as an essential component in mediating these functions, more recent developments in the neurosciences have also led to an increased appreciation for the essential role that is played by extensive cerebral interconnections between subcortical and cortical regions of the brain.

An underlying executive component is implied in many of the techniques discussed above. For example, as assessed on a serial addition task, complex attention depends on shifting focus and sustaining a cognitive set flexibly. Standard expressive language measures of verbal fluency are highly dependent on the individual's ability to self-activate and maintain a productive flow of responses without losing the cognitive set. Memory functions rely on processing information efficiently, including using higher-order processing strategies to organize incoming information (e.g., clustering words in a memory list based on semantic categories). Memory deficits attributed to retrieval failure in the information processing model of memory are often associated with executive deficits. However, some specific techniques have gained favor over the years as primary measures of executive functions.

The *Wisconsin Card Sorting Test* (WCST) requires an individual to sort a long series of cards with designs according to various principles that can only be gleaned by incorporating feedback from the examiner. This measure, then, assesses the individual's ability to generate and test various solutions, flexibly respond to changing circumstances, and integrate new information with experience to respond as efficiently as possible. The *Category Test* from the Halstead–Reitan Battery is less commonly used to assess the individual's flexibility to incorporate feedback into problem-solving responses. The *Delis-Kaplan Executive Function System* (D-KEFS) is based on several other techniques associated with executive abilities. These include variations on the *Trail-Making Test, Verbal Fluency Test, Design Fluency Test, Color-Word Interference Test, Sorting Test, Twenty Questions Test, Word Context Test, Tower Test,* and *Proverb Test.*

Psychological Factors

A key component of any neuropsychological examination involves considering the degree to which longstanding personality or other psychological factors (including current stressors) might contribute to the patient's presentation. Common techniques for assessing personality and psychological factors include paper and pencil techniques, such as the *Beck Depression Inventory-II, Geriatric Depression Scale,* and *the Minnesota Multiphasic Personality Inventory*, which is now in the 3rd edition; however, the 2nd edition and the *Revised Form* are still commonly used (MMPI-2/RF/3*).* In addition, the *Personality Assessment Inventory* (PAI) is another more extended personality inventory that has become increasingly used by neuropsychologists in recent years.

Performance and Symptom Validity

To ensure the validity of the neuropsychological assessment, the neuropsychologist needs to evaluate performance and symptom validity as a standard part of every assessment. Performance validity refers to the credibility of examinee performance on cognitive tests, while symptom validity refers to the veracity of symptom endorsement.

When the test data raise concerns about validity, the neuropsychologist faces a sensitive diagnostic scenario since it is difficult to differentiate between nonconscious factors that can result in noncredible responding versus intentional exaggeration of symptoms (e.g., factitious disorder or malingering). Researchers have proposed several sets of criteria that help clinicians think about the possibility of malingering by considering discrepancies between test data and the examinee's self-report, in contrast to known patterns of brain functioning, observed behavior, reliable collateral reports, and documented background history. In addition, poor performance on performance validity tests (PVTs) or signs of psychiatric, cognitive, or somatic overreporting on symptom validity tests (SVTs) would also add weight to the possibility of noncredible responding or outright malingering.

Several free-standing PVTs exist, including forced-choice measures such as Green's *Word Memory Test* and the *Test of Memory Malingering.* The forced-choice measures are beneficial at discerning intentionality, as significantly below chance performance provides the most substantial evidence for bona fide malingering. Nonforced choice measures also include *Rey's 15-Item Memory Test* and the *Dot Counting Test.* Still, other performance validity measures can be found embedded within other standard neuropsychological procedures. These PVTs share a foundation based on normative research that indicates that patients with histories of bona fide brain injury or even dementia can be expected to perform at adequate levels on these instruments. Poor performance on a PVT suggests that factors other than brain injury alone should be considered as possible explanations. Other indicators of performance validity are based on the pattern of an individual's performance on standard procedures in a neuropsychological examination. For example, because it is always easier to recognize than to freely recall memory material, comparing an examinee's performance on recognition and recall offers a means for assessing the possibility of poor effort. In general, a patient's level of effort is best evaluated in the context of the broader history and pattern of neuropsychological performance, so it would not make sense to administer PVTs in isolation. An experienced clinical neuropsychologist will avoid equating poor performance on PVTs with "malingering" and instead use these results to think about factors other than brain injury or outright malingering that might influence an examinee's performance.

Commonly used SVTs include those embedded within the more extended personality inventories used by neuropsychologists (i.e., MMPI-2/RF/3 or PAI), but freestanding SVTs also exist, such as the Structured Inventory of Malingering Symptomatology (SIMS). The F-family scales within the MMPI-2/RF/3 encompass scales that assess overreporting of psychiatric, somatic, and cognitive symptoms. In addition to the F-family scales, the MMPI-2/RF/3 also includes the Response Bias Scale (RBS), which was derived to be uniquely indicative of feigned cognitive dysfunction. The MMPI-2/RF/3 also includes a few SVTs indicative of under-reporting of psychiatric symptoms. The PAI includes several SVTs that assess the presence of over and under-reporting of symptoms, including the recently derived Cognitive Bias Scale (CBS), which has been shown to operate similarly to the RBS. Therefore, it can be beneficial for neuropsychologists.

A 32-year-old woman with 13 years of education was seen for disability evaluation, claiming current “trouble remembering things.” Her account of personal history was vague, and she “forgot” information, such as her birth date and mother’s maiden name. Response latencies were extremely long, even for highly familiar information (e.g., count from 1 to 20), she could not repeat more than three digits forward consistently, and on a word list learning procedure, she was not able to correctly recognize more items (only five) than she could freely recall (also five). Despite her otherwise fluent language, she could only generate five examples of animals in 1 minute. On a forced-choice PVT, she performed significantly below chance levels. When she was asked to recall 15 items on a procedure (Rey’s 15-Item Memory Test) that the examiner presented as challenging, although, in reality, it is relatively simple, her performance demonstrated exaggerated errors of commission. On objective personality testing (i.e., MMPI-2-RF), the RBS scale was significantly elevated. The evaluation concluded that current levels of cognitive functioning could not be conclusively established due to overt noncredible performance.

THERAPEUTIC DISCUSSION OF RESULTS

A vital component of the neuropsychological examination process is found in the therapeutic opportunity to discuss the examination results with the patient and family or other caregivers. This meeting can represent a powerful therapeutic opportunity to educate and clarify individual and relationship issues, impacting the identified patient’s functioning. If the patient’s active cooperation in the initial examination has been appropriately enlisted, then the patient will be prepared to invest value and confidence in the examination findings. When discussing the results, it is helpful to review the examination goals with the patient and supportive family or caregivers and clarify the expectations of those present. Typically, these sessions will include information about the patient’s diagnosis, emphasizing the natural course and prognosis as well as compensation and coping strategies for the patient and family. Given the impact of chronic neurologic disease upon the family system and the patient, explicit discussion of these issues is critical in maximizing adjustment to brain injury. It is equally important to discuss the impact of the results on the patient's current living circumstances, future goals, and course of adjustment. It is not unusual for strong emotions and underlying tensions within family relationships to come to light in the context of honest discussion. So the results discussion can represent a significant therapeutic opportunity to model effective communication and problem-solving techniques.

The most challenging discussions usually arise when the objective examination results do not meet the preconceived beliefs of the patient or family members. In such cases, it is helpful to begin the feedback discussion by first asking the patient to describe their impression of their performance to identify the patient's perspective and associated expectations explicitly. For those persons who appear to be strongly invested in confirming a pathologic diagnosis of memory impairment, it may be beneficial to adopt a psychoeducational approach by using materials such as the Information Processing Model of Memory presented in Figure 7.4–3.

7.5 Personality Assessment of Adults

Russell L. Adams, Ph.D., A.B.P.P-NP., C.L., and David L. Adams, Psy.D., B.C.B.A.-D.

Although the term personality has been defined in various ways over the years, in this chapter, personality is defined as an individual's enduring and pervasive motivations, emotions, interpersonal skills, attitudes, and traits. The systematic empirical measurement of personality traits is the purview of personality assessment. Most personality tests are norm based and have specified reliability and validity. A given test's reliability and validity together with the size and nature of the normative base largely determine its usefulness.

For a given personality test to be accepted, the test developer must demonstrate how reliable the test is and how valid it is. Reliability refers to the consistency with which a given individual would obtain the same or similar score if given the same test or a parallel version of the same test was administered again. Under similar circumstances, the validity of a given test refers to the degree to which the test measures what it purports to measure. In other words, does a personality test measuring depression differentiate effectively between individuals who independently have been determined to have no depression, mild, moderate, or severe depression? A valid depression test should be able to measure changes in depression that may occur over time with effective treatment.

The systematic measurement of such difficult-to-define personality traits as depression and anxiety can be challenging. Particularly difficult is assessing characteristics such as suicide potential, impulsivity, or inability to delay gratification.

Personality tests are used for a variety of purposes. A personality test can screen or identify individuals in need of treatment or intervention. Personality tests can also be used to assist in the differential diagnosis of a given patient, especially when the patient does not fit neatly in one of the DSM-5 categories. Some personality tests can help inform the clinician concerning what treatment might be most effective. Personality tests can also monitor the progress of a given patient in treatment over time.

Personality tests are used extensively in the medical–legal context. For example, is a given patient suffering psychologically from a severe motor vehicle accident? Does that patient have post-traumatic stress disorder (PTSD)? Some personality tests are also used to identify individuals who are over- or underreporting psychological symptomatology.

PURPOSES OF PSYCHOLOGICAL TESTING

Personality testing can be an expensive undertaking. A considerable amount of time is required to administer, score, and interpret psychological test results. Personality testing should not be routinely obtained from all psychiatric patients, especially in today's cost-containment environment. Nevertheless, personality testing can be helpful with selective patients from both a clinical and a cost-benefit analysis perspective.

Assisting in Differential Diagnosis

As any clinician knows, psychiatric diagnosis can be a difficult and, at times, confusing exercise. However, knowing a patient's diagnosis is essential to treatment, as a proper diagnosis can assist in understanding the etiology of the presenting psychiatric problem and the prognosis of the disorder. Consider the diagnostic dilemma in the following example:

> A 49-year-old White man had abruptly resigned his position as an accountant and decided he was going to start an oil exploration business. He had never worked in the oil business and knew nothing about the profession. The patient had received a revelation from an unknown entity through an auditory hallucination. This voice told him he would become quite wealthy in the business if he would simply follow the directions given to him. Around this time, the patient had a marked change in personality. Although his grooming was formerly very neat and appropriate, he became disheveled. He began sleeping about 3 hours a night. He became somewhat agitated and talked loudly to those around him.

The differential diagnosis in this case illustration includes schizophrenia and bipolar disorder. Psychological testing might be helpful in assisting in this differential diagnosis, as well as in formulating a treatment plan.

Aiding in Psychotherapy

Psychological tests can be useful in psychotherapy. The usefulness of these tests can be even more important for short-term, problem-centered therapy where understanding the patient and their problem must be accomplished quickly. Psychological assessment can be used in pretreatment planning, assessing progress once therapy begins, and in evaluating the effectiveness of therapy. Patients need to have objective information about themselves at the time of therapy if they are to go about changing themselves productively. Personality tests, particularly objective tests, allow patients to compare themselves to objective norms and evaluate the extent and magnitude of their problem. Testing also can reveal areas of the patient's life that may be problematic but for which the patient may not have a full appreciation. Information about patients' willingness to reveal information about themselves can also be helpful. In some instances, the test report can be the subject of an early treatment session. Psychological tests may reveal considerable information concerning the patient's inner life, feelings, and images, which may make therapy progress faster. Psychological testing can provide baseline information at the beginning of therapy, and repeat testing can then be used to assess change that occurred during the course of therapy.

Providing Narrow-Band Assessment

Narrow-band personality tests measure a single personality characteristic or a few related characteristics. Broad-band personality tests, on the other hand, are designed to measure a wide spectrum of personality characteristics. A psychiatrist may need answers to specific questions, such as those that arise when assessing the degree of clinical depression, measuring the intensity of the state or trait anxiety, or, possibly, quantifying the amount of a patient's anger. Such quantification can be helpful in measuring severity or in providing a baseline for future assessment.

Psychological tests can often assist with a specific problem area. For example, a young college student may be unsure what to major in. Vocational interest inventories, such as the Strong Vocational Interest Inventory and the Kuder Occupational Interest Survey, may help to better define the student’s vocational interest. The Strong Vocational Interest Inventory compares a given individual’s responses with those of a large group of successful individuals in a variety of occupations. Test results can show that a student’s interests are similar, for example, to those of successful persons in occupations such as social work or public administration and dissimilar to those of engineers or scientists.

PSYCHOMETRIC PROPERTIES OF PERSONALITY ASSESSMENT INSTRUMENTS

The quality of personality tests varies widely. On the one hand, there are well-constructed, empirically validated instruments, and, on the other hand, there are “psychological tests” that one can find in the Sunday supplement of the newspaper or on the internet. Evaluating the usefulness of particular psychological instruments can be challenging, even to the well informed.

Just as the *Physician’s Desk Reference* helps physicians evaluate the usefulness of medications, the *Buros Mental Measurement Yearbook* helps psychologists evaluate the usefulness of personality instruments and other psychological and achievement tests. The *Mental Measurement Yearbook* is a reference source of critical reviews of individual tests. These reviews evaluate the scientific underpinnings of each test by an expert in the field. The reviews generally address such issues as the reliability and validity of the tests, the normative group used in construction, and various empirical studies utilized to check out the reliability and validity of the instrument. The advantages and disadvantages of the test are described. The reviews generally describe situations in which the test can be appropriately used. Practical information concerning the test publisher, length of time of administration, and other considerations are also included. The *Buros Mental Measurement Yearbook* is available in most medical school and university libraries and can be ordered through the book’s publisher.

Normative Sample

To construct a personality test, a representative sample of subjects (normative sample) should be administered the test to establish expected performance. Basic issues, such as the size and representativeness of the sample used to construct the test, must be evaluated. A sample of 30 individuals of a given diagnosis in a single location is seldom appropriate, because there are so many moderating factors impacting results, such as age, education, sex, and racial and ethnic grouping. These factors frequently impact the norms, and appropriate controls must be made for these variables in many cases.

To illustrate this point, the Minnesota Multiphasic Personality Inventory 2 (MMPI-2), a well-constructed instrument, initially tested approximately 2,900 subjects. However, approximately 300 subjects were eliminated because of test invalidity or incompleteness of needed information. The final group was comprised of 2,600 community volunteers, including 1,462 women and 1,138 men. The MMPI-2 normative group was selected using census data as a guide and was broadly representative in terms of region of the country, racial composition, age, and formal education. Despite efforts to control for moderating variables, the sample was slightly overrepresentative in higher education levels. Obviously, the cost of obtaining large census-based normative samples is enormous, and few tests are able to meet these challenging criteria. Nevertheless, many tests that fall short of the national sample (and most do) can be useful in the hands of an experienced clinician who is sensitive to the problem and makes appropriate clinical adjustments in interpreting the results.

Test Characteristics

To be useful, any psychological test must be completed, in its entirety, by the intended test taker. If the questions are offensive or are difficult to understand, then the individual taking the test may not complete all items. These omissions can create problems, especially when normative tables are used to interpret results. To be useful, an instrument should be short enough to complete in a relatively short period of time. The Beck Depression Inventory or the Geriatric Depression Scale can each be easily completed in 5 to 10 minutes. Because of its short length, the test can be given repeatedly to a depressed patient in treatment to monitor changes over time. The MMPI-2, on the other hand, takes approximately 1 to 1½ hours to complete. This test is not appropriate for repeat testing over a short period of time. Most tests are easily scored and compared to normative tables.

Validity Issues

Perhaps the most important characteristic in evaluating the scientific merit of a given personality test is the validity of the instrument. Does the test measure what it purports to measure? If a test is designed to measure depression, does it indeed measure depression? Although validity may seem like a simple issue to address, it can become complex, especially when attempting to measure such characteristics as self-esteem, assertiveness, hostility, or self-control. The test developer must first operationally define what is meant by the personality characteristic in question. A number of different approaches have been used to measure validity, including face validity, logical content validity, construct validity, criterion validity, and factor validity.

Face Validity. *Face validity* refers to the content of the test items themselves. In other words, do the items appear to measure what they purport to measure? For example, does a depression scale ask questions concerning sadness, guilt, sleep disturbance, weight loss, helplessness, hopelessness, or suicidal thoughts? One problem with face validity is that professionals differ in their subjective appraisal of individual items. One psychologist may think a given item does, indeed, measure the concept under consideration, while other professionals may not. To address these differences in definition, the test developers may utilize an approach known as *logical content validity*. Using this approach, the developer will describe in the manual the procedure used to select items for the test that will not depend significantly on the subjective judgment of any one professional. For example, in developing the Taylor Manifest Anxiety Scales, a number of different psychologists were asked to review items from the MMPI that seemed to measure a formal definition of manifest anxiety, and only those items agreed on by this group of psychologists were included. Many creative approaches have been used to demonstrate the logical content validity of various tests.

Criteria and Construct Validity. Although face validity refers to the degree that test items appear on the surface to measure what the instrument, as a whole, purports to measure, *criterion validity* uses data outside the test itself to measure validity. For example, if a test were designed to measure hypochondria, one would expect that a patient with high scores would have more visits to the physician’s office, complain of more physical symptoms, and use prescribed and over-the-counter medications more extensively. These criteria are objective and external to the test itself and can be independently measured. Scores on the hypochondria instrument can be statistically correlated with a number of separate objective criteria, such as those mentioned previously, to determine if the test measures the theoretical construct being measured (*construct validity*).

Concurrent and Predictive Validity. To determine test *concurrent validity*, external measures are obtained at the same time that the test is given to the sample of subjects. Thus, the concurrent validity of the test reveals that, at a given point of time, high scorers on a test may be more likely than low scorers on a test to manifest the behavior reflected in the criteria (e.g., more physician visits or more medication for a hypochondriac patient). Occasionally, however, a test developer is interested in predicting future events. For example, a test designed to predict marital satisfaction among engaged couples may use the couples' future marital satisfaction and marital status as an external criterion. Thus, the external criterion would have to be obtained a number of years down the road for the test to have this predictive validity. This type of validity is referred to as *predictive validity*. Because it is difficult to obtain such information several years later, predictive validity is seldom available in most personality tests, although such data can be valuable when available.

The *discriminant validity* of a test tells whether the test is able to discriminate between known groups of patients at a given time. For example, is a test of depression able to statistically discriminate nondepressed subjects from subjects who suffer from independently diagnosed major depression, adjustment disorder with depressed mood, and dysthymia? Is a measure of depression able to statistically discriminate among mild, moderate, and severe major depressive disorder?

Factor Validity. Factor validity utilizes a multivariate statistical technique known as *factor analysis* to determine if certain major groups of items on a given test empirically cluster together. For example, on a personality test measuring depression, do items concerning vegetative symptoms tend to covary together? Are there other clusters of items on the depression test measuring cognitive problems, mood disturbance, and social withdrawal?

Reliability

To be useful, a test must not only be valid, but it must also be reliable. *Reliability* refers to the degree that a test measures what it purports to measure, consistently. The key word here is *consistently.* For example, a patient with agoraphobia takes a new agoraphobia test today and takes the same test tomorrow. However, on the second testing, the scores change markedly even though the patient had not received any treatment or undergone any change in their underlying agoraphobia. Such a test would not be useful, because it would not consistently measure the trait in question. The test would have poor reliability. There are several means of checking reliability, including test–retest reliability, internal consistency reliability, and parallel form reliability.

Test–Retest Reliability. *Test–retest reliability* is obtained by simply administering the same test on two occasions to a group of subjects and statistically correlating the results. To be useful, the correlation coefficient should be at least 0.80 if the two tests were administered within 2 weeks of each other and if the trait in question is stable.

Internal Consistency Reliability. Another approach to determine *internal consistency reliability* is to divide a given test into two equal parts and statistically correlate the two halves for the test with each other. This technique determines the *split-half reliability* of a test. The first half of the test should be highly correlated with the second half of the test if the test is consistently measuring what it purportedly measures. Alternatively, the odd-numbered items could be correlated with the even-numbered items (*odd–even consistency or reliability*). When a test is split into two parts and the obtained scores correlate with each other, the resulting correlation coefficients statistically underestimate the true reliability of the test because the number of items in the test influences the magnitude of the correlation. Hence, if there were only half that number of items in the original test, then the results would be underestimated. To correct for this underestimation, the *Spearman–Brown formula* is used. Again, a reliability coefficient of 0.80 to 0.85 is needed to demonstrate usefulness in most circumstances. However, the higher the reliability as measured by the correlation coefficient, the better the test instrument. No test is perfectly reliable. The highest possible correlation coefficient is 1.0, and the lowest is 0, assuming no negative correlation.

To determine how internally consistent a given test is, a test developer also may use a statistical technique called *Cronbach's coefficient alpha*. With Cronbach's coefficient alpha statistic, one can determine the average correlation among all the items on the test. The higher the average correlation, the better the reliability.

Parallel Form Reliability. Sometimes, two separate forms of the same test are needed. For example, if the process of taking a test at one point in time would by itself influence a patient's score the second time that they took the same test, then parallel forms of the test are needed. *Parallel forms* of a test measure the same construct but use different items to do so. To ensure that the test does, in fact, measure the same construct, the correlation coefficient between the two parallel forms of the same test is computed. Such parallel form reliability should be at least 0.90 or higher.

Use of Standard Error of Measurement to Assess Reliability. Another way to assess the usefulness of a given test is to examine the test's standard error of measurement (SEM), which should be included in the test's manual. The SEM is a single statistic that is used to estimate what the score of a given patient would be on the test if the patient took the same test again within a short period of time. Consider the following example: A patient takes a given test today and obtains a score of 90 on that test. The SEM on that test is 3. An SEM value of 3 together with an individual's score of 90 on the test means that if that patient were to take that same test again tomorrow, they would score within ± 1 SEM of their original test performance (e.g., ±3 points) 68% of the time. Thus, the patient in question should score between 87 (90 − 3) and 93 (90 + 3) on the second test 68% of the time. The same individual would score ±2 SEM values (e.g., 2 × 3 = 6) on the second test 95% of the time.

In the above example, the patient with an original score of 90 on a given test would score between 84 (90 − 6) and 96 (90 + 6) on the second test again 95% of the time. Other things being equal, the smaller the SEM relative to the standard deviation of the tests, the better.

ADULT PSYCHOLOGICAL TESTS

Objective Personality Tests

Objective personality tests are rather straightforward in approach. Patients are usually asked specific and standard questions in a structured written or oral format. Each patient is typically asked the same question. The data obtained from a given patient are compared to similar data obtained from the normative group. The degree to which the patient deviates from the norm is noted and is used in the interpretive process. The patient's responses are scored according to certain agreed-upon criteria. The obtained scores are then compared with normative tables and often converted to standardized scores or percentiles, or both. The MMPI-2 is an example of an objective personality test.

There are literally hundreds of different objective personality instruments, and discussing all of these instruments is beyond the scope of this section. Table 7.5–1 contains a representative sample of objective personality tests and concise descriptions of each test, along with a brief listing of strengths and weaknesses. Because the MMPI-2 is, by far, the most frequently used objective personality test, it is discussed in considerable detail in this section to give the reader an orientation to objective personality assessment, as well as objective personality development.

This focus on the MMPI-2 is not meant to imply that the MMPI-2 is the only valid and reliable objective personality instrument or that other objective personality tests are not as useful as the MMPI-2 for a particular purpose. There are many useful objective personality instruments.

Minnesota Multiphasic Personality Inventory-2. Two excellent books on the MMPI-2 are James N. Butcher's *The MMPI-2 in Psychological Treatment* and John R. Graham's *MMPI-2 Assessing Personality and Psychopathology*. The following discussion relies heavily on information contained in these two resources. The MMPI-2 consists of 567 true/false questions concerning a wide variety of issues. The patient completes the test using a pencil. The MMPI-2 is relatively easy to administer and score and takes approximately 1 to 1½ hours for most patients to complete. It requires only an eighth-grade reading comprehension. The test provides a number of internal checks for measuring the patient's degree of cooperation. The patient is simply asked to answer true and false to such questions as "I have a good appetite," or "No one seems to understand me."

Scoring of the MMPI-2 involves adding up the number of responses on numerous scales and comparing the results to certain normative information. Interpretation of the MMPI-2 is more straightforward than with many other tests, because of the vast amount of empirical information available concerning the MMPI-2. More than 12,000 articles and books have been published on this test to date.

There are over 115 translations of the MMPI-2. The test is also cost-effective, because relatively little professional time is involved in the administration and scoring. The patient is simply given instructions, and then they complete the test independently in the professional's office. In certain situations, the MMPI-2 can be administered on the computer. A computer can also plot test profiles and compute various supplemental scales. The number of available specialized scales increases the usefulness of the MMPI-2 with various populations (e.g., patients with PTSD, college students who are maladjusted, and prisoners with violent tendencies).

Questions cover a wide range of different areas. When a patient takes the MMPI-2, questions are not grouped in any particular order to aid in interpretation. Various items in the MMPI-2 can be selected, sorted, and analyzed according to various criteria. The most common scales of the MMPI-2, including the validity scales, clinical scales, content scales, supplemental scales, and critical items, are discussed below.

VALIDITY SCALES. The patient can approach a mental status interview in a variety of ways. The patient can be painfully honest and straightforward with the interviewer, revealing their innermost aspirations and fears. The patient may be somewhat distrusting of the interviewer and may try to slant the content of the interview in a certain fashion to manipulate the outcome they want. The patient may be disingenuous or even attempt to be deceitful by malingering. Obviously, the information obtained by psychiatrists or other mental health professionals in an interview may well be colored by the patient's approach to the interview. Some patients are, by their nature, reserved and may use denial successfully during a clinical interview. Other patients may have little insight into their feelings and thoughts. Many times, a psychiatrist may not know how candid or straightforward a patient is during an interview.

When patients are administered personality tests like the MMPI-2, they approach the test in a similar fashion to how they approach an interview.

One advantage of the MMPI-2 is that the test has been devised to assess different test-taking attitudes (e.g., fake bad, fake good, or social desirability responding). Through use of the validity scales, the clinician gleans information that helps in interpreting the remaining scales of the MMPI-2. Is the patient overly defensive? Are they attempting to fake good or fake bad? Does the patient maintain a reasonable balance between self-disclosure and excessive defensiveness?

Lie (L) Scale. This scale consists of 15 items designed to measure general frankness. The items include questions concerning personal characteristics that, although highly desirable in our culture, are, nevertheless, infrequently practiced (e.g., questions such as, "I have never failed to tell the truth," or "Once in a while I think of things too bad to talk about," and "I do not always tell the truth"). Patients who score high on the lie scale may be psychologically naive or defensive. They may want to be seen in a positive light or they may have difficulty admitting common human frailties.

F-Scale. This is one of the longest scales, consisting of 60 items that 10% or fewer of the normative samples responded to in the positive direction. This scale includes such items as follows: "Evil spirits possess me at times," and "Most any time I would rather sit and daydream than do anything else."

The items on the F-Scale are quite diverse in content and may be indicative of severe psychopathology such as hallucinations or delusions. Most people in the normal sample responded to fewer than five of these items. Individuals who obtain exceptionally high scores on this scale are often either extremely pathologic or trying to claim mental illness falsely. As with all personality tests, interpretation depends greatly on the setting in which the test was given, as base rates for different settings and circumstances differ. For example, patients who have been seen for court sanity evaluations have different base rates of symptom magnification than do patients seen for adjustment problems in an outpatient clinic.

Table 7.5–1.
Objective Measures of Personality

Name	Description	Strengths	Weaknesses
Minnesota Multiphasic Personality Inventory-2 (MMPI-2)	567 items; true–false; self-report format; 20 primary scales	Large research base; most known and utilized objective personality assessment instrument; provides considerable clinically useful information while requiring limited clinician time	Required that the patient be able to read items, comprehend instructions, and follow direction; some patients attempt to fabricate responses but validity scales available
Minnesota Multiphasic Personality Inventory-3 (MMPI-3)	335 items; includes 72 new items with 52 scales and 10 validity scales; takes 25–35 minutes to administer	Spanish version available; large national diverse normative sample; based on a long extensive history with the respected MMPI and MMPI-2; can be computer-administered with an empirically based interpretative report	Relatively new test without the strong independent research base enjoyed by the MMPI and MMPI-2; unclear if previous research of MMPI-2 will apply, as the structure of the tests is slightly different than previous versions
Clinical Multiaxial Inventory-III (MCMI-III)	175 items; true–false; self-report format; 25 primary scales	Brief administration time; corresponds well with DSM-IV	High degree of item overlaps in various scales; may overdiagnose pathology in some cases through

			many scale elevations
16 Personality Factor Questionnaire (16 PF)	True–false; self-report format; 16 personality dimensions	Sophisticated psychometric instrument with considerable research conducted on nonclinical populations	Limited usefulness with clinical populations
Personality Assessment Inventory (PAI)	344 items; Likert-type format; self-report; 22 scales	Includes measures of psychopathology, personality dimensions, validity scales, and specific concerns to psychotherapeutic treatment	The inventory is increasingly being utilized, but it does not currently have the strong research basis found in the MMPI-2
Personality Inventory for DSM-5 (PID-5)	220 items; Likert-type format; 25 personality trait facets with 5 broad trait domains	Corresponds to the 25 personality traits outlined in the DSM-5	Additional research warranted
NEO Personality Inventory-Revised (NEO PI-R)	240 items with 3 validity scales	Corresponds to the Five Factor Model for personality	Requires a 6th-grade reading level
California Personality Inventory (CPI)	434 questions - true–false; self-report	Well-accepted method of assessing patients who do	Limited usefulness with clinical populations

	format; 20 "folk" scales of character with 4 classes	not present with major psychopathology	
Jackson Personality Inventory (JPI-R)	300 questions–true–false; self-report format; 15 personality scales	Constructed in accord with sophisticated psychometric techniques; controls for response sets	Unproved usefulness in clinical settings
Edwards Personal Preference Schedule (EPPS)	Forced choice; self-report format	Follows Murray's theory of personology; accounts for social desirability; measures 15 personal needs; often used in vocational counseling	Not widely used clinically because of restricted nature of information obtained
Psychological Screening Inventory (PSI-2)	139 items; true–false; self-report format	Yields 4 Basic Screening Scales, 21 Brief Content Scales, and 6 Misrepresentation Scales; can be used as screening measures concerning the possibility of a person's need for psychological treatment	The scales are short and have correspondingly limited reliability
Eysenck	Utilizes	Useful as a	Scales are short,

Personality Questionnaire (EPQ)	yes/no questions (48 questions in short version; 100 in longer version); self-report format	screening device; test has a theoretical basis with research support; measures personality traits using 4 scales	and items are transparent as to purpose; not recommended for other than a screening device
Adjective Checklist (ACL)	True–false; self-report or informant report	Can be used for self-rating or other rating; measures 37 traits and each of these scales are grouped into 6 Success Factors at work	Scores rarely correlate highly with conventional personality inventories
Comrey Personality Scales (CPS)	True–false; self-report format; 10 scales, including the validity check scales; 180 items	Factor analytic techniques used in test construction	Not widely used; factor analytic interpretation problems
Tennessee Self-Concept Scale (TSCS:2), 2nd edition	100 items; true-false; self-report format; 15 scales	Brief administration time yields considerable information; measures self-concept in 15 scales, which includes 4 validity scales	Brevity is also a disadvantage, lowering reliability and validity; useful as a screening device only

Adapted and revised from Robert W. Butler, Ph.D., and Paul Satz, Ph.D.

Backpage Infrequency Scale. A few patients, particularly those with passive–aggressive tendencies, will start to complete the MMPI-2 but, toward the end of the test, may respond to the items in a random fashion. The patient may simply want to finish the test quickly and leave the testing situation. The Backpage Infrequency (Fb) scale for the MMPI-2 is designed to pick up this tendency.

Variable Response Inconsistency Scale. The Variable Response Inconsistency Scale VRIN consists of 67 pairs of items. Each question of the pair probes for the same or similar information in a slightly different way, for example: (1) “I sleep very poorly at night,” and (2) “I wake up fully refreshed each morning.” If the patient responds “true” to question 1, then they would normally respond “false” to question 2. Failure to do so would reflect inconsistency.

CLINICAL SCALES. The clinical scales are generally considered the meat or substance of MMPI-2 clinical interpretations. The original clinical scales have an empirical base in the sense that the items were selected because they differentiated between specific clinical groups and the normative control group. The control group for the original MMPI, developed in the 1940s, consisted of 1,500 persons who were visitors to the University of Minnesota hospitals and other normal groups. Clinical groups varied in size but, for the most part, contained at least 50 subjects. For example, the schizophrenic scale group was developed with patients with different types of schizophrenia, and the depression scale was developed with a sample of psychiatric patients with depression, including some with manic depressive illness. Table 7.5–2 presents a brief illustration of the original sample groups. Although most clinical scales were developed using a specific clinically defined group, researchers with the MMPI soon learned that a given patient (such as one with schizophrenia) did not simply score high on the schizophrenia scale and low on all other scales. A schizophrenic patient might score high on many scales, but their highest score may well be the schizophrenic scale. If one were to diagnose all patients who scored high on the schizophrenic scales as schizophrenic patients, then a large number of false positives would result. To address this confusion, clinicians began to refer to the clinical scales by a number

(0 to 9) rather than the diagnostic entity that underlies the scale's development.

COMBINING SCALE ELEVATIONS IN THE CODE TYPES. As has been illustrated previously, interpreting single-scale evaluations on the MMPI-2 is problematic; thus, most clinicians use a combination of scale elevations in interpretation. This procedure usually involves using the patient's highest two clinical scales that exceed a *t* score of 65 to provide a configured interpretation that takes into account the relation between the scales. In this approach, for example, a 1-2 or 2-1 code type would be the same. In other words, a patient who scored highest on scale 1 (hypochondriasis [Hs]) and second highest on scale 2 (depression [D]) would be considered to have the same basic profile as an individual who scored highest on scale 2 (D) and second highest on scale 1 (Hs).

A three-point code, likewise, would list the three highest scales, all of which normally would be above a *t* score of 65. These scales also would usually be significantly higher than all of the other clinical scales.

On the MMPI-2, uniform *t* scores are used on clinical scales except in scales 5 (masculinity/femininity) and 0 (social introversion). *Uniform t scores*, briefly stated, are standardized scores in which the percentile equivalent and distribution are matched among the various clinical scales in terms of skewness and kurtosis. Thus, a uniform *t* score of 65 on scale 7 (psychasthenia) is roughly equivalent to a uniform *t* score of 65 on scale 9 (hypomania). The use of uniform *t* score rather than linear *t* scores was one of the improvements of the MMPI-2 over the original MMPI.

Table 7.5–2.
Minnesota Multiphasic Personality Inventory Scale Development

Scale 1—(**Hs: Hypochrondriasis**): The clinical group of this scale consisted of patients who had an obsessive overconcern about their physical health.

Scale 2—(**D: Depression**): This group consisted of a variety of patients with symptomatic depression, including reactive depression and manic depression among others.

Scale 3—(**Hy: Hysteria**): The hysteria group consisted of patients who had some type of sensorimotor deficit for which no organic basis could be found.

Scale 4—(**Pd: Psychopathic Deviancy**): This patient group had continual run-ins with legal authorities, yet they had normal intelligence and no serious neurotic or psychotic symptomatology. No major criminal types were included. These patients exhibited delinquent acts such as stealing, lying, excessive drinking, and sexual promiscuity.

Scale 5—(**Mf: Masculinity–Femininity**): This scale originally was developed to discriminate homosexual invert males. However, there were only a small number of items that statistically differentiated this group from the controls. As a result, other items were included that differentiated men from women in the normative sample.

Scale 6—(**Pa: Paranoia**): Patients in this group consisted of suspicious, mistrusting individuals who often had diagnoses other than paranoia. These persons could have a paranoid personality, paranoid schizophrenia, or an affective disorder. Interestingly, the scale had few false positives, but had a rather large number of false negatives.

Scale 7—(**Pt: Psychasthenia**): This scale was originally developed using a group of patients with psychasthenia. This diagnosis is no longer used today but does resemble a diagnosis of obsessive-compulsive disorder. These patients worry excessively; have major fears, compulsions, and rituals; and possess generalized anxiety and distress.

Scale 8—(**Sc: Schizophrenia**): The patient group used for this scale consisted of various types of schizophrenic patients. Efforts to develop separate scales for different subtypes of schizophrenia were not successful.

Scale 9—(**Ma: Mania**): Because patients who have full-blown mania are not testable, this scale was developed utilizing patients who were in the earlier stages of manic episodes.

Scale 0—(**Si: Social Introversion**): This scale was not developed on a particular diagnostic group. Rather the items were determined by contrasting selected females who scored in the high or low range on another measure of social introversion. Social Introversion–Extraversion scale of the Minnesota TSE (Thinking–Social–Emotional) Inventory.

Data from Graham J. *MMPI–2 Assessing Personality and Psychopathology*. Oxford University Press; 1990.

A review of the interpretation of common two- and three-code types can be found in most standard textbooks on the MMPI, some of which are included in the references. Certain MMPI authorities have used slightly more complex means of interpreting the MMPI-2. This approach emphasizes specific relationships about multiple scales. For example, Harold Gilderstadt and Jan Duker described criteria in their book *A Handbook for Clinical and Actuarial MMPI Interpretation* for what is referred to as a *1,2,3,4-type scale*, as follows:

1. Hs, D, Hy, and Pd greater than *t* score 70 and higher than all other scales.
2. Si less than *t* score of 70.
3. L, F, and K less than *t* score 70 unless two or more scales are greater than 100, in which case F less than *t* score 80.

The problem in using this complex method is that, in many settings, only a relatively small percentage of patients match these criteria. In other words, if one uses this method rigidly, then a substantial number of patients seen in an inpatient unit would not precisely match one of these complex criteria.

CONTENT SCALES FOR MMPI-2. Several efforts have been made to group items according to certain specified dimensions. Using a combination of rational and statistical procedures, Butcher and colleagues developed these 15 narrow-band scales. The 15 scales are internally consistent and relatively independent. Item overlap between scales is minimal. Scales include such content areas as anxiety, anger, cynicism, low self-esteem, fears, obsessiveness, and depression among many others. Norms for both males and females were simply derived using the same uniform *t* scores used in the MMPI-2 clinical scale formation. Reliability data on the scales are acceptable given the relatively few items in some of the content scales.

John R. Graham presents scoring guidelines in his book *MMPI-2 Assessing Personality and Psychopathology*. Validity data for the new scales are limited at the current time. Because efforts were made to develop reasonably homogeneous items, interpretation of these scales consists of examining high scores and low scores. For example, patients with high scores on the low self-esteem scale tend to have poor self-concept, anticipate failure, be overly sensitive to criticism, and have trouble making decisions. Individuals with low scores, on the other hand, are self-confident and decisive. A given content scale such as the anger scale, when considered alone, is very similar to the rapid assessment instruments discussed in a later section of this chapter.

HARRIS & LINGOES CONTENT SCALES. As previously stated, most of the MMPI clinical scales were developed using empirical key approaches. For example, an item was included in the depression scale because that item discriminated patients in the reference group from persons in the normal group. Although this method is scientifically sound, the approach results in the inclusion of subtle items that seemingly may have little to do with depression. For example, items such as, “I sometimes tease animals,” (false) and, “It takes a lot of argument to convince most people of the truth,” (false) are included in the depression scale (D) even though, on the surface, they have little to do with depression. Such items are called *subtle items*. Obvious items are those that have strong face validity, such as, “I wish I could be as happy as others,” (true) and, “I brood a great deal” (true). The depression subscale reflects a heterogeneous item group coming from a variety of aspects of depression, such as subjective depression, psychomotor retardation, mental dullness, etc. The same total score might reflect a considerably different combination of items. Knowing which items in combination actually contribute to the total score can be helpful in interpretation. The Harris & Lingoes scale can help in that process.

The Harris & Lingoes scales were developed logically by grouping items in a given clinical scale into standard scales that were judged to reflect a more homogeneous trait. Thus, the Harris & Lingoes scales for depression reflect separate scales for subjective depression (D1), psychomotor retardation (D2), physical malfunction (D3), mental dullness (D4), and brooding (D5).

The Harris & Lingoes scales can be used for two major purposes: (1) to see which group of items was elevated for a patient scoring high on a given clinical scale and (2) to see why a marginally elevated scale was elevated. For example, one patient who scored marginally high on the depression scale may be demonstrating psychomotor retardation and no subjective depression while another may be just the opposite.

SUPPLEMENTAL SCALES. Given the MMPI contained 567 items, numerous investigators have used the items to develop special purpose or supplemental scales. As early as 1972, more than 450 supplemental scales were developed, and the number has kept growing. Scales have been developed to predict success in psychotherapy (ego strength [Es]), to differentiate alcoholic patients from nonalcoholic patients (MacAndrew Revised [MACR]), and to differentiate assaultive prisoners from others not committing a crime (overcontrolled hostility [Oh]). Many dissertations for doctoral research have been conducted to uncover a new supplemental scale. The success of supplemental scales in accomplishing their stated purpose varies considerably. Many such scales were utilized for only one study, and others, such as the MacAndrew Alcoholism (MAC) scale, have been used in many studies over the years.

COMPUTER SCORING AND INTERPRETATION. A computer program can score the MMPI-2. A typical computer scoring program not only scores individual items into validity, clinical, content, and supplemental scales but also prints out certain positive critical items marked by the patient. These programs save considerable time because the program scores all of the material that may take hours to score by hand. Few clinicians have the time or patience to routinely score the vast number of scales found in the output of a typical computer program. The MMPI-2 computer programs can also be used to interpret the test clinically, or at least give clinical hypotheses concerning the patient. These computer-generated reports are in narrative format. Because the report comes from a computer, one may get the impression that the information is more valid or accurate than a clinical interpretation. Although attempts have been made to “validate” narrative statements made by the computer, efforts have only begun in this regard. One problem with computer interpretation of narrative reports is that the algorithms underlying the narrative reports are proprietary information owned by the company producing the program and are not available to the general user.

MMPI-2-Restructured Form. Yossef S. Ben-Porath and Auke Tellegen have developed a version of the MMPI-2 called the MMPI-2-Restructured Form (RF). Unlike the MMPI-2, which contains 567 items, the RF version contains 338 items; consequently, it takes less time to administer. The MMPI-2-RF has 51 revised empirically validated scales. The test is designed to take 35 to 50 minutes for most patients to complete. The MMPI-2-RF is not a replacement of the well-validated MMPI-2 test but instead provides an alternative instrument. The MMPI-2-RF has the Restructured Clinical (RC) scales at its core. The 51 scales comprising the MMPI-2-RF include eight different validity scales including a new Fake Bad Scale revised (FBS-r) symptom validity scale and three higher-order scales, such as the Thought Dysfunction Scale (THD).

As previously mentioned, the nine RC scales are at its core. The RC scales include an Antisocial Behavior Scale (RC-4) as well as an Ideas of Persecution Scale (RC-6).

In addition to the aforementioned scales, there are 3 different somatic scales, 10 internalizing scales, and 4 externalizing scales. In order to assess interpersonal issues, five different scales are provided, including the family problems scale. There are also two interest scales and five personality psychopathology scales.

Most mental health professionals use the computer for scoring because hand scoring is much too time-consuming and subject to some scorer errors. If the 567 items in the MMPI-2 are administered to a given patient, then a special software program converts the MMPI-2 scores to an MMPI-2-RF record.

The Minnesota Multiphasic Personality Inventory-3. The Minnesota Multiphasic Personality Inventory-3 (MMPI-3), the most recent version of the MMPI, was published in 2020 by the University of Minnesota press. A primary goal of the MMPI-3 was to update the norms to keep up with the changing demographics in the United States. According to the technical manual, the MMPI-3 was normed on 1,620 subjects selected to match the U.S. Census projections for race and ethnicity. The normative individuals (810 women and 810 men) were at least 18 years old. The normative sample was diverse, consisting of 60.3% White, 12.4% Black, 5.1% Asian, 14% Hispanic, 4.5% mixed-race, and 3.7% other racial-ethnic groups. Similarly, the sample matches the current census distribution in the United States for age. A special Spanish translation of the MMPI-3 is also available. This version was derived from a normative sample of U.S. Spanish speakers that included 275 men and 271 women.

In addition to having new norms, the 335-item MMPI-3 includes 72 new items that were not in previous versions and 24 reworded items that were included in previous versions but were updated in more contemporary language. The MMPI-3 has fewer items than the original MMPI and therefore can be administered in 25 to 30 minutes by a computer or 35 to 50 minutes with the paper and pencil version.

The MMPI-3 has 52 scales, 5 of which are completely new and not in previous versions. The new scales were designed to assess Combined Response Inconsistency (CRIN), Eating Concerns (EAT), Compulsivity (CMP), Impulsivity (IMP), and Self-Importance (SFI). The 52 scales include 10 validity scales, 3 higher-order scales, 8 RC scales, 26 Specific Problem Scales, and 5 Psychopathology Scales. The MMPI-3 is normally scored by the computer, and an interpreted report can also be generated.

Although the MMPI-3 is the most recent version, the MMPI-2 is still being published by Pearson and currently is regularly used by many psychologists if not most psychologists. The MMPI-2 has a long history with thousands of independently conducted research investigations supporting its continued use in a wide variety of clinical situations. At this point, psychologists can confidently use either version based on their preference.

The Personality Inventory for DSM-5—Adult. As stated in DSM-5, the diagnosis of personality disorders is a difficult and confusing endeavor. The problems include the fact that a given patient frequently meets criteria for more than one personality disorder. Moreover, the patient may not formally meet the criteria for any single personality disorder, but instead receive a diagnosis of “other specified” or “unspecified personality disorder.” Although this may be the correct diagnosis, it is mostly uninformative in terms of treatment or prognosis.

An alternative model for personality disorders is presented in DSM-5. This alternative model is found in Section III of the DSM-5 under “Emerging Measures and Models.” The current approach to personality disorders still appears in Section II of DSM-5. A complete discussion of this alternative DSM-5 model is beyond the scope of this chapter on personality assessment.

Briefly, the Section III Multidimensional Personality Trait model involves assessing a given patient on five broad domains of personality and 25 traits. This approach uses a formal psychometric rating instrument entitled "Personality Inventory for DSM-5" (PID-5), which is a self-report inventory completed by the patient and/or another similar form completed by a significant other in the person's life Personality Inventory for DSM-5-Informant-Report Form (PID-5-IRF).

This PID-5 consists of 220 questions. The Personality Disorders Workgroup of the DSM-5 developed it in 2012. It consists of a Likert scale with the following rating system: 0 (very false), 1 (somewhat false), 2 (somewhat true), and 3 (very true). The scoring of this instrument provides a raw score on five domains (negative affect, detachment, antagonism, disinhibition, and psychoticism). In addition, the PID-5 provides information on one of 25 personality trait facets including anhedonia, anxiousness, attention seeking, callousness, deceitfulness, depressivity, distractibility, eccentricity, emotional lability, grandiosity, hostility, impulsivity, intimacy avoidance, irresponsibility, manipulativeness, perceptual dysregulation, perseveration, restricted affectivity, rigid perfectionism, risk taking, separation insecurity, submissiveness, suspiciousness, unusual beliefs and experiences, and withdrawal. An average raw score is calculated for each of the five domains and each of the 25 personality trait facets. Higher average raw scores on a particular trait or domain indicate greater dysfunction.

The major advantage of the PID-5 is that it is directly tied to the DSM-5 model for personality disorders. Second, this instrument is a very easy scale for clinicians to administer. Third, it holds much promise for future research investigation.

The available research of the PID-5 is limited at the current time. In addition, the rating reliability of a practicing clinician is not known at the current time. Moreover, the interrater reliability of practicing clinicians using this measure has not yet been established.

There are also some shorter versions of the PID-5, including the PID-5-SF, the PID-5 faceted brief form (PID-5-FBF), and the PID-5-BF. The PID-5-SF version and the PID-5BF only have 100 questions, as compared to the 220 questions in the PID-5. The American Psychiatric Association published the PID-5-BF. The PID-5-BF measures five personality traits including detachment, negative affect, antagonism, disinhibition, and psychoticism, with a version for children between the ages of 11 through 17 years of age and another one for adults. This instrument only has 25 questions. However, there are limited studies demonstrating the reliability and validity of all the shorter versions.

Millon Clinical Multiaxial Inventory-III. Published in 1994, the Millon Clinical Multiaxial Inventory-III (MCMI-III) is an objective psychological test consisting of 175 true–false questions designed to measure psychopathology. The MCMI-III was updated in 2008 to include a new norming sample of 752 individuals with a diversity of mental health conditions. The MCMI-III should only be used with adults over the age of 18 with suspected mental health conditions. This instrument was standardized with psychiatric patients with mental health problems, so it should not be used with nonclinical populations. The MCMI-III is particularly effective with describing personality disorders.

The scales correspond to the 14 personality disorders and 10 clinical scales outlined in the DSM-IV. In addition, this instrument has 42 Grossman Faucet Scales (3 scales for each of the 14 personality disorders). Therefore, this instrument has a large number of scales for a limited number of items. The MCMI-III uses five Correction scales: the Disclosure Scale (X), the Desirability Scale (Y), the Debasement Scale (Z), the Invalidity Scale (V), and the Inconsistency Scale (W). These five correction scales help to determine the validity of the assessment based on the responses of the patient.

The advantages of this instrument are that it is quite easy to administer and only takes approximately 30 to 45 minutes to complete the test. The computerized narrative can be helpful to the clinician. One complaint concerning this test is that it may over diagnose pathology through many scale elevations.

Personality Inventory-Revised. Developed by Costa and McCrae, the NEO Personality Inventory Revised (NEO-PI-R) is a personality assessment that is based upon the Big Five Personality domains (openness to experience, conscientiousness, extraversion, agreeableness, neuroticism). These five personality domains are also known as the Five Factor Model (FFM). This instrument contains 240 items and is designed to take approximately 30 to 45 minutes to complete. The patient must be able to read on the sixth-grade level. The NEO-PI-R was published in 1990, and the NEO-PI-3 is the most up-to-date version of the NEO-PI-R.

There is a brief version of the NEO-PI-R that was revised in 2004 called the NEO-FFI. The NEO-FFI published the most recent update in 2010. The NEO-FFI only has 60 items (consisting of 12 items in each domain), and it takes 10 to 15 minutes to complete.

Personality Assessment Inventory. Another increasingly popular objective personality test is the Personality Assessment Inventory (PAI). This test consists of 344 items that are written at a fourth-grade reading level. This reading level ensures that most patients can complete it without experiencing any reading problems. The PAI takes about 45 to 50 minutes to complete for most patients. The PAI was normed on 1,000 community-dwelling individuals stratified according to gender, race, and age. There are not separate norms for male and female as there are in the MMPI. In addition, data were gathered on 1,246 clinical subjects and 1,051 college students in the normative process. The clinical subjects were drawn from a variety of different clinical settings, including inpatient psychiatric facilities (25%), outpatient psychiatric facilities (35%), correctional institutions (12%), medical settings (2%), and substance abuse treatment programs (15%).

Unlike the MMPI-2 where the patient is asked simply to answer whether a given item is true or false for them, the PAI allows for four alternative responses from the patient. The patient is asked if a given item for them is totally false, slightly true, mainly true, or very true.

Similarly to the MMPI-2, the PAI has four validity scales that measure the degree to which the patient is attempting to present themself in an overly positive or overly negative fashion. In other words, is the patient trying to feign psychopathology (fake bad) or underreport symptoms (fake good)? If the patient is attempting to fake bad or fake good, then the resulting PAI profile would of course likely be invalid and could not be interpreted.

The PAI has 11 clinical scales. These main clinical scales are similar to the MMPI-2 clinical scales and measure such personality issues as somatic concerns, depression, paranoia, borderline features, or alcohol or drug problems. The PAI also has five treatment-related scales that are designed to address such issues as treatment rejection, suicide ideation, or aggression. Two PAI interpersonal scales measure dominance and warmth.

Several strengths of the PAI are that the scales are nonoverlapping, the reading level is low, and four response choices to individual items are given. The MMPI-2 and PAI are not to be used as diagnostic instruments by themselves, but diagnosis determination needs to be based on a clinical interview and historical and medical information as well.

Rapid Personality Assessment Instruments. Rapid personality assessment instruments are narrow-spectrum self-report objective instruments that measure some unidimensional aspect of personality. The instrument is written in clear, simple language and provides face validity. Typically, these short instruments can be completed in less than 15 minutes. The scoring is simple and straightforward, usually just adding up the number of positive responses. On many instruments, there are cutting scores, above which an individual is considered to have a clinically significant problem in that area.

There are literally hundreds of such measures capable of assessing a wide variety of personality states and traits, such as geriatric depression, obsessive-compulsiveness, impulsivity, and state-trait anger. Table 7.5–3 presents common examples of such measures. The overall score typically provides an index of the magnitude of the patient's problems. Most of these tests can be used repeatedly to assess change over time. A number of instruments were developed using relatively small samples and have limited scientific studies documenting their usefulness in a variety of situations.

Some rapid assessment instruments were developed out of the behavioral assessment tradition. One advantage of short personality assessment procedures is high face validity for the domain of the behavior in question. Most instruments have standardized instructions and small normative groups. Performances of patients with the psychiatric problem in question (anger dyscontrol or geriatric depression) are frequently reported in terms of mean performance and standard deviation. One can find a rapid assessment instrument to assess many of the common psychiatric problems seen today. Another advantage of these instruments is the ease of administration and scoring. The major disadvantage is that these instruments differ greatly in their reliability and validity. Normative groups are frequently small and are obtained in one location. Most do not have national samples. Many of these short instruments have few, if any, studies of their construct validity. Most instruments do not systematically assess response styles such as faking bad, faking good, or social desirability responding. Examples of the hundreds of rapid assessments include measures of bulimia, obsessive-compulsive behavior, sexual functioning, fear and panic, and personal beliefs.

Projective Personality Tests

Projective personality tests, in contrast to objective personality instruments, are more indirect and unstructured. Unlike objective tests in which the patient may simply mark “true” or “false” to given questions, the variety of responses to projective personality tests are almost unlimited. Instructions are usually very general in nature, allowing the patient’s fantasies to be expressed. The patient generally does not know how their responses will be scored or analyzed. Consequently, trying to feign the test becomes difficult. Projective tests typically do not usually measure one particular personality characteristic such as “type A personality” (e.g., narrow-band measurement) but instead are designed to assess one’s personality as a whole (e.g., broad-band measurement).

Projective tests often focus on “latent” or unconscious aspects of personality. Obviously, psychologists and others differ in the degree to which they rely on “unconscious” information. In many projective techniques, the patient is simply shown a picture of something and asked to tell what the picture reminds them of. An underlying assumption of projective techniques (projective hypothesis) is that when presented with an ambiguous stimulus, such as an inkblot, for which there are an almost unlimited number of responses, the patient’s responses will reflect fundamental aspects of their personality. The ambiguous stimulus is a sort of screen on which the individual projects their own needs, thoughts, or conflicts. Different persons have different thoughts, needs, and conflicts and, hence, have widely different responses. The responses of a schizophrenic patient often reflect a rather bizarre, idiosyncratic view of the world.

Table 7.5–3.
Rapid Personality Instruments

Name	Description	Strengths	Weaknesses
Geriatric Depression Scale	30 items covering depression in the elderly; given orally or written; does not emphasize the vegetative signs of depression	Has reasonably good internal consistency reliability; good concurrent validity with other measures; can distinguish between normal, mildly depressed, and severely depressed patient	Geriatric patients frequently unwilling to admit depression because of denial; normative data limited
Beck Depression Inventory II	21 self-administered items for assessing depression in persons having at least a sixth-grade education; originally designed for use with trained interviewers, the test is self-administered; can assess the severity of depression; sensitive to changes due to psychotherapy and medication; measures patient	Large number of studies available in the literature establishes both its test–retest reliability and validity; widely used	No validity scales to assess approach to testing; is not specific to depression; patients with other disorders may score high on the test

	change weekly during therapy; assessed depression during specified period of 1 week; alpha coefficients were reported to be in the high 0.80s; effective in discriminating mild, moderate, and severe depression		
State Trait Anxiety Inventory	Anxiety is conceptualized as subjective tension and worry along with heightened arousal of the autonomic nervous system; state anxiety is the amount of anxiety a person has at a given moment in time; trait anxiety refers to the degree of anxiety a person usually experiences; there are 2 separate but similarly worded instruments, one measuring state anxiety (S Anxiety) the other measuring trait anxiety (T Anxiety); both consist of 20 questions	Very large normative sample of more than 5,000 in one study; inventory translated in many languages; excellent internal consistency reliability and concurrent validity	No validity scales; patients who score high on anxiety also frequently score high on depression and other psychological measure instruments
Michigan	Designed to screen for	Most frequently	Extensive

Alcoholism Screening Test (MAST-R)	alcoholism and problem drinking, presumably in people not manifesting suffering from these problems; the revised version has 25 items that can be completed in 10 minutes	used screening instrument for alcoholism; high internal consistency and good test–retest reliability; discriminates controls from other alcoholic problem groups (hospitalized alcoholics, driving under the influence offenders, persons convicted of drinking and disorderly conduct)	norms of population not available; may overdiagnose alcoholism in some cases and produced high false positive rates, particularly in college students; lack of candor on part of respondent can impact usefulness; high face validity makes it easy to fabricate responses
McGill Pain Questionnaire (MPQ)	The purpose of the MPQ is to assess quantitatively the qualitative characteristics of pain; instrument consists of 78 adjectives that the patient marks concerning the sensory, affective,	Used with patients suffering from all types of pain; can be used to assess effectiveness of various pain treatments	Adjectives can be hard for individuals with low educational background and/or low IQ to understand; pain complaints

	and evaluative nature of pain along with other characteristics; a pain rating index and pain intensity score is calculated; there is an MPQ-2 short version available, too (SF-MPQ-2)	(medication, biofeedback, relaxation exercise, surgery); has been used to discriminate between patients who have pain associated with objective physical findings and individuals who have pain without such findings	can be easily malingered

There are literally hundreds of different projective techniques developed—most of which are not widely used today. Table 7.5–4 contains a list of common projective tests together with a description of the tests. The strengths and weaknesses of the projective tests are also presented. This section will focus on more widely used projective instruments such as the Rorschach test, Thematic Apperception Test (TAT), and sentence completion.

The literature on projective techniques is vast, and the history of projective techniques goes back for many years. Arthur Carr pointed out in the fourth edition of the *Comprehensive Textbook of Psychiatry* that Shakespeare had an appreciation of the importance of one's association to ambiguous stimuli. In an effort to feign insanity, Hamlet associated to a cloud formation certain images that presumably reflected his personality.

Rorschach Test. Herman Rorschach, a Swiss psychiatrist, developed the first major use of projective techniques around 1910. The Rorschach test is the most frequently used projective personality instrument (Fig. 7.5–1). The test consists of 10 ambiguous symmetrical inkblots. The inkblot card appears as if a blot of ink was poured onto a piece of paper and folded over—hence, the symmetrical appearance. These 6½- × 9½-inch inkblot cards are the standard stimuli and, by convention, are referred to as Roman numerals I to X.

Table 7.5–4.
Projective Measures of Personality

Name	Description	Strengths	Weaknesses
Rorschach test	10 stimulus cards of inkblots, some colored, others achromatic	Most widely used projective device and certainly the best researched; considerable interpretative data available	Some Rorschach interpretive systems have unproven validity
Thematic Apperception Test (TAT)	20 stimulus cards depicting a number of scenes of varying ambiguity	A widely used method that, in the hands of a well-trained person, provides valuable information	No generally accepted scoring system results in poor consistency in interpretation; time-consuming administration
Sentence completion test	A number of different devices available, all sharing the same format with more similarities than differences	Brief administration time; can be a useful adjunct to clinical interviews if supplied beforehand	Stimuli are obvious as to intent and subject to easy falsification
Holtzman Inkblot Technique (HIT)	Two parallel forms of inkblot cards with 45 cards per form	Only one response is allowed per card, making research less troublesome	Not widely accepted and rarely used; not directly comparable to Rorschach interpretive strategies
Figure drawing	Typically, human	Quick	Interpretive

	forms but can involve houses or other forms	administration	strategies have typically been unsupported by research
Make-a-Picture Story (MAPS)	Similar to TAT; however, stimuli can be manipulated by the patient	Provides idiographic personality information through thematic analysis	Minimal research support; not widely used

Courtesy of Robert W. Butler, Ph.D., and Paul Satz, Ph.D.

Using John E. Exner's Comprehensive System, the examiner, in essence, gives the patient the following instructions: "You'll be given a series of inkblots. Look at each inkblot and tell me what you see." The examiner gives the patient each card and asks, "What might this be?"

Minimal interaction between the examiner and the patient occurs while the Rorschach is administered, which ensures standardization procedures are upheld. The examiner writes down verbatim what the patient says during the above-described "free association" or "response proper" phase. If the patient rotates the card during their response, then the examiner makes the appropriate notation on the test protocol. After the patient has given responses to all 10 cards, an inquiry phase of administration begins. The examiner asks the patient to go through the cards again and help the examiner see the responses they gave. The examiner reads the patient's initial response and asks the patient to point out what they saw and explain what made it look like that to them. An almost unlimited range of responses is possible with the Rorschach test and most projective tests. Six different scoring and interpretation systems for the Rorschach test are available for the clinician; however, Exner's Comprehensive System is the most widely used and accepted. A structural summary of the various measures derived from the patient's response is usually computed.

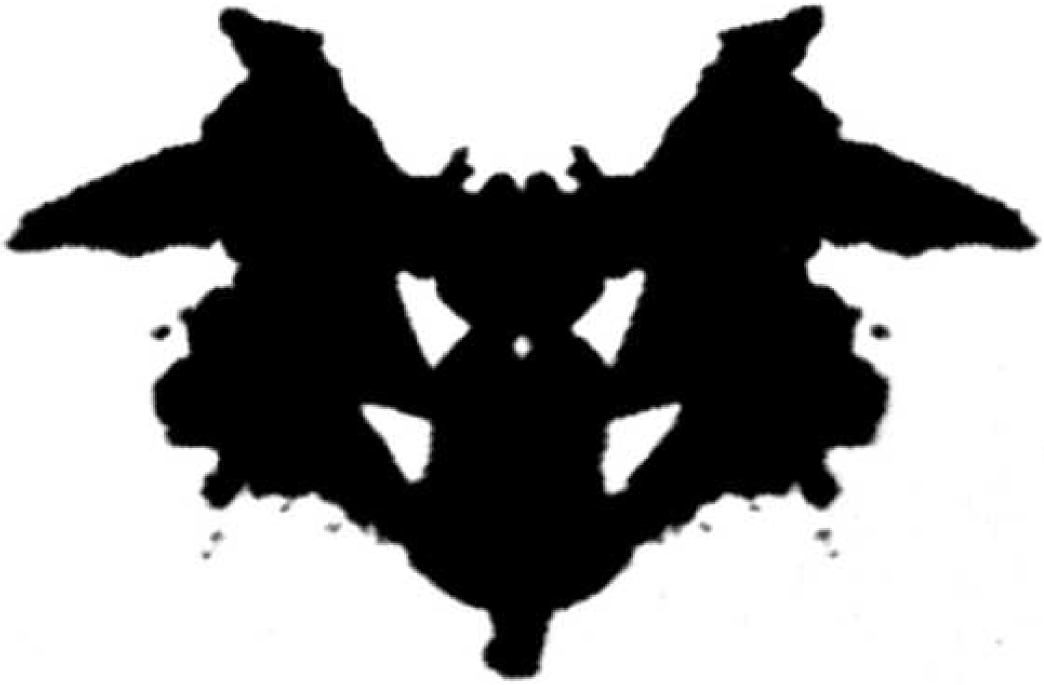

FIGURE 7.5–1. Card I of the Rorschach test. (From Hermann Rorschach, Rorschach®-Test. Copyright © Verlag Hans Huber, Hogrefe Verlag Bern, Switzerland, 1921, 1948, 1994, 2017, with permission.)

Scoring and interpretation of the Rorschach test can be a time-consuming process. Administering and scoring the Rorschach test usually takes about 1½ to 2 hours of time. Typically, examiners score the Rorschach responses according to the *location* on the blot where the patient sees the response. The factors that make patients respond the way that they did are referred to as the *determinants* (shape of blot, color, and shading). The examiner also scores the actual *content* of the patient's response (e.g., animals or human anatomy). The scoring system is elaborate and can result in dozens of different indices being computed. Although some investigators question the reliability of certain measures, many studies do support the usefulness of the Rorschach test as a personality assessment instrument in the hands of a qualified and experienced psychologist.

The limited scientific support of the Rorschach test, however, has resulted in critical reviews by some psychologists. A number of graduate schools of clinical psychology no longer offer formal coursework in the Rorschach test, although many still do.

Table 7.5–5 gives the sample Rorschach responses of a number of patients to Rorschach card I. Notice how different the responses are by various patients to this same card and how the responses reflect the patient's underlying personality.

Table 7.5–6 shows certain cluster variables derived from Exner's Comprehensive Scoring System. The interpretive utility of these cluster variables is also described in the table.

Thematic Apperception Test. Although the Rorschach test is clearly the most frequently used projective personality test, the TAT is probably in second place. Many clinicians will include both the TAT and the Rorschach test in a battery of tests for personality assessment. The TAT consists of a series of 10 black-and-white pictures that depict individuals of both sexes and of different age groups, who are involved in a variety of different activities. For example, on Card 1, a young boy is shown sitting at a table, looking at a violin. Card 2 depicts a farm scene in which a young woman is in the foreground carrying books in her hands. A man is working in the fields nearby, and an older woman is seen in the background. Typically, a patient is shown 10 TAT cards and is asked to make up stories about them. The patient is asked to tell what is going on in the picture, what is going on before the picture was taken, what the individuals in the picture are thinking and feeling, and what is likely to happen in the future.

Table 7.5–5.

Sample Rorschach Responses and Interpretation to Card 1 by Diagnostic Category

Diagnostic Category	**Response Proper**	**Inquiry**	**Interpretation**
Nonpatient	Well, the first impression is of a wolf's head, ears here and eyes.	Overall, the head, nose, eyes, ears, the whole thing.	Common response utilizing the white space as the eyes, responding to the whole blot.
"Schizo" patient	I will say the first thing that comes to mind, it would be a predator on the movie, loss of ink, predator, have you seen that movie?	The whole picture all the way, and I liked the movie, and the reason why is because you said the first thing that comes to mind. I've seen the movie over and over again, ten times. The whole picture, something that looks at me mean (Looks at you mean?) Because it's a person that kills without any feeling, that's why I thought the movie was good.	The response shows difficulty staying focused on the task at hand, tangential thought process, some paranoia and distortion of the form of the card.
Depression	Could be a leaf.	Could be a leaf that has fallen off the tree and started to decay, leafs have jagged edges (You said decayed?) Because if it was a perfect leaf all this would be part of the blot, and here parts of it that have fallen off. That would have been the stem. Also, you have the main vein running down the middle, this is more	The response shows morbid content (decay) that indicates a poor view of self and the world. Leaf responses also weigh on the isolation index.

		prevalent because it’s biggest, if it was on a tree, it would get nutrients to the leaf like our blood system.	
Anxiety	I don’t know, I’d have to think about it. It could be trees.	Like if you are in the forest, stalks you know, when trees bland together they are nondescript. I’m a real outdoor person, I like to go to the forest and spend time there. (Can you help me see the trees?) Just this little Christmas tree here and here, the outline.	The response shows discomfort in committing to a response, and discomfort in beginning the task. Some anxiety is also seen in the rambling personalization used to justify the response.

Courtesy of Dana Stelter, Ph.D., Clinical Psychologist.

Henry Murray developed the TAT in 1943 at the Harvard Psychological Clinic. The stories that the patient makes up concerning the pictures, according to the projective hypothesis, reflect the patient’s own needs, thoughts, feelings, stresses, wishes, desires, and view of the future. According to the theory underlying the test, a patient identifies with a particular individual in the picture. This individual is called the *hero*. The hero is usually close to the age of the patient and frequently of the same sex, although not necessarily so. Theoretically, the patient would attribute their own needs, thoughts, and feelings to this hero. The forces present in the hero’s environment represent the *press* of the story, and the *outcome* is the resolution of the interaction between the hero’s needs and desires and the press of the environment. The TAT, in the hands of a skilled interpreter, can reveal considerable information about the patient’s personality that can then be combined with other information obtained from the interview and other testing.

Table 7.5–6.
Cluster Variables (Exner System) and Basic Interpretive Utility

Cluster Variable	Interpretive Value
Control Stress Tolerance	Can assess a person's stress tolerance, ability to control their behavior, and responses in the environment.
Situation-Related Stress	Can assess the amount of situational stress affecting a person's capacity for control.
Affective Features	Can assess how a person manages emotional stimuli, types of emotional features such as depression and anger, and ability to modulate their affect.
Self-Perception	Can assess how a person views themselves and ability to look at themselves.
Interpersonal Perception	Can assess how a person views others, ways they interact with others, and how well they identify with others.
Information Processing	Can assess how a person organizes information in their world and how they process it.
Cognitive Mediation	Can assess the conventionality of a person's perceptions and degree of reality distortions.
Ideation	Can assess aspects of ideation such as processing style, use of defenses such as fantasy and intellectualization, and if their thoughts proceed in logical, coherent fashion or have some thought slippage.

Courtesy of Dana Stelter, Ph.D., Clinical Psychologist.

By itself, the TAT is not an effective diagnostic instrument, nor was it designed to be. Moreover, as measured by traditional methods of assessing reliability and validity, the TAT lacks the scientific merit of objective instruments. The fact that it has remained reasonably popular today, however, speaks to the instrument's usefulness in clinical practice.

Sentence Completion Test. Although a projective instrument, the sentence completion test is much more direct in soliciting responses from the patient. They are simply presented with a series of incomplete sentences and is asked to complete the sentence with the first response that comes to mind. The following are examples of possible incomplete sentences:

My father seldom …
Most people don’t know that I’m afraid of …
When I was a child, I …
When encountering frustration, I usually…

The purpose of the test is to elicit, in a somewhat indirect manner, information about the patient that cannot be elicited from other measures. Because the patient responds in writing, the examiner’s time is limited. The length of time it takes to complete the sentence completion varies greatly depending on the number of incomplete sentences. Tests can range from less than 10 sentences to greater than 75.

There are many variations of sentence completion tests. Some clinicians have developed their own tests. One form of the test, developed by Julian Rotter, has some established validity and reliability, but most sentence completion tests do not. Special purpose sentence completion tests have been developed to measure different problem areas. For example, there is a sentence completion test that is used with patients who have chronic pain. The sentence completion test is seldom, if ever, used alone but is combined with other appropriate instruments.

Advantages of the sentence completion test are short administration time, ease of administration, variety of instruments, and ease of construction. Disadvantages are lack of reliability and validity studies and ease of fabrication and deception.

Behavioral Assessment

Behavioral assessment involves the direct measurement of a given behavior. Rather than focus primarily on human characteristics, such as repression, ego strength, or self-esteem (vague terms to a behaviorist), strict behavioral measurement concentrates on the direct measurement that can be observed, such as a number of temper tantrums per unit of time, duration and intensity and number of hyperventilation episodes, or the number of cigarettes smoked per 24-hour period.

Although early strict behaviorists would count only behaviors that were observable, a broader definition of behavior has emerged, under which just about anything people do—whether it is overt such as crying, swearing, or handwashing or covert such as feeling and thinking—is considered behavior. To measure covert behavior, the patient is typically the informant. For example, to measure dysfunctional thinking, the patient may simply carry a mechanical counter and press it every time they have a particular target self-disparaging thought during a given unit of time.

Direct Behavioral Measurement. The patient, a family member, or an impartial observer can measure behavior directly. Therapists use direct behavioral measurements to establish baselines of a given undesirable behavior (i.e., violent thoughts that the patient may wish to reduce). Similarly, therapists can measure behavior that the patient wants to increase (time studying or distance walked on a treadmill). Follow-up measures of the same behavior monitor progress and quantify improvement.

Different aspects of a target behavior can be counted or measured, such as frequency of behavior (e.g., number of behavioral occurrences), duration of behavior (length of time behavior occurred), and intensity. Event recording is a behavior measurement technique in which an individual counts instances of behavior. This approach is best used for discrete behaviors that have a beginning and end. For example, one can count the number of instances of nail-biting, the number of times out of bed, the number of occasions one arrives late to work, or the number of dysfunctional thoughts they have concerning an employer during a given 18-hour period.

Interval Recording is another type of behavioral measurement technique that can be used to measure how often a behavior occurs. Sometimes it is not feasible to count each instance of behavior as the behavior may be too frequent. In addition, certain behaviors may not be discrete (with a beginning and end) such as the duration of time an individual stays on task on a work project.

There are three types of interval recording. In momentary time sampling, one records whether or not the behavior occurred at a particular time. For example, every 15 minutes, one records whether or not the behavior is occurring at that particular moment. Momentary time sampling is best use for very high-frequency behaviors. The second type of interval recording is called whole interval recording. In whole interval recording, one divides a time segment into many intervals (e.g., 30 intervals consisting of 15 seconds for each interval). An interval is scored only if the behavior occurred during the entire interval. Whole interval recording is used for behaviors that one wishes to increase, but it tends to underestimate the duration of the behavior. Partial interval recording is set up as the same as whole interval recording, but the interval is scored if the behavior occurs anytime in the interval. This type of interval recording is best used for behaviors to decrease, and this approach tends to overestimate the occurrence of the behavior. Whole and partial interval recording will provide one with the percentage of intervals a behavior occurs (e.g., 15% of intervals).

The advantage of using event recording and interval recording is that it is direct, objective, and easily understood and quantifies the degree of behavioral change. The problem with counting specific behaviors is that many patients have so many different symptoms it would not be possible to quantify them all. Sometimes, the process of counting a target behavior may itself alter the behavior. It can also be used to help increase awareness of behavioral patterns.

Rating Scales

Rating scales have been developed to detect various aspects of personality. On some of these scales, the patient simply rates themself on a given scale dimension such as sadness, 1 = I am not sad, or 7 = I wish I were dead. On other scales, a significant other person is asked to rate the patient, 1 = the individual seldom mentions being sad, or 7 = the individual says they would be better off dead. Some of the more commonly used rating scales, however, are designed to quantify information obtained by the mental health professional during a mental status interview.

Brief Psychiatric Rating Scale. One of the more commonly used rating scales is a Brief Psychiatric Rating Scale (BPRS). To use the BPRS, the psychologist or psychiatrist simply completes a mental status interview with the patient. After completing the interview, the interviewer rates the patient on a series of 18 psychiatric symptoms, such as motor retardation, blunted affect, conceptual disorganization, anxiety, and guilt.

Expanded definitions of each of these terms are provided to the examiner. The interviewer rates each domain on a seven-point Likert scale from “not present,” the lowest rating, to “extremely severe,” the highest rating. An experienced interviewer can complete the ratings in 2 or 3 minutes. The BPRS has been used extensively in drug outcome and other studies. The advantage of the BPRS is that the interrater reliability is reasonably high for a rating scale of this nature. A summary article of over 300 studies utilizing the BPRS found interrater reliability correlative of 0.80 or higher on the total score in the majority of studies. The first author has used this instrument to teach medical students to be observant of a patient’s behavior, and relatively inexperienced medical students can establish reasonably good reliability. Other advantages of the BPRS include the ease and speed of rating and well-defined symptom description.

One disadvantage of this scale is examiner subjectivity. Another disadvantage is that the interviewer can only rate the patient on what they personally observes during the interview. Examiners differ greatly in their style of conducting a mental status interview, and thus, one examiner might ask many questions on interviews in one given area (i.e., somatic concern), while nearly overlooking another area (i.e., suspiciousness). Another examiner might do just the opposite.

Integrated Psychological Assessment to Answer Specific Referral Questions

Normally in the practice of medicine, a physician evaluates a patient’s chief complaints, signs, and symptoms. On the basis of this information, the physician may suspect a given medical problem. In order to further investigate, the physician may order a series of lab tests or other studies to further delineate the problem at hand. For example, a physician may suspect that a patient has a dysfunctional liver and consequently orders liver function tests. Test results are reported back to the physician in terms of quantitative information that helps the treating physician to better understand the nature of the patient’s problems.

In contrast, in requesting a psychological assessment, it is normally better for the psychiatrist or other health professional to ask the psychologist specific referral questions rather than specify particular tests to be administered. Below are listed examples of referral questions:

1. What is the patient’s DSM-5 diagnosis?

2. Is the patient psychotic?
3. Does this patient have schizophrenia or bipolar disorder?
4. Does this patient have an attention deficit disorder or are their presenting problems due to anxiety?
5. Does the patient have the cognitive and personality resources to assist in their own defense in a criminal case?
6. Is this patient feigning a psychiatric disorder or do they, in fact, have a genuine disorder?

In order to answer the referral question, the psychologist will determine which tests are most appropriate given the nature of the referral question(s). There are literally hundreds of different psychological tests that may be utilized to answer various referral questions. After conducting a biopsychosocial assessment, a mental status evaluation, and personality testing, and perhaps an interview with a significant other person in the patient’s life, a psychologist will integrate this information in a comprehensive psychological assessment report in order to answer the psychiatrist’s specific referral question. In this case, the goal is not simply to report back to the psychiatrist a series of isolated scores, but rather the goal is to interpret the scores in relationship to a referral question that the psychiatrist posed. By using this approach, the psychiatrist is most likely to have their referral question answered. In order to answer specific referral questions, the psychologist may utilize personality tests, but they may also utilize cognitive, achievement, and narrowband tests. In some cases, it may be necessary to order specialized neuropsychological testing in order to answer the referral question. When a neuropsychological test is required, the evaluation is normally completed by a neuropsychologist who has special training and experience in brain–behavior relationships.

Psychologists will often have the patient complete a comprehensive battery consisting of different tests to answer the referral question. For example, based on a specific referral question concerning a psychiatric diagnosis, a psychologist may choose a battery of tests that include the MMPI-2, MCMI-3, and the Beck Depression Inventory-2. The psychologist will write a comprehensive report that presents the findings of psychological testing and a summary and recommendations section that addresses the specific referral question.

7.6 Medical Assessment and Laboratory Testing in Psychiatry

JENNIFER L. KRUSE, M.D., AND JOHN O. BROOKS, III, PH.D., M.D.

The goal of this section is to outline laboratory tests, neuroimaging studies, and other assessments applicable to psychiatric practice and the strategies for using them in an effective manner. The role of imaging studies, the electroencephalogram (EEG), various biochemical, hematologic, endocrine, immunologic, and toxicologic assessments are discussed. A logical and systematic approach to the use of these tools by the psychiatrist is vital to achieving the goals of arriving at accurate diagnoses, identifying medical comorbidities, implementing appropriate treatment, and delivering cost-effective care. With respect to the diagnosis or management of medical disease, consultation with colleagues in other specialties is important. Medical specialists also are a useful source of information about test methodology and the proper performance and interpretation of tests. Analogous consultation with appropriate specialists is important when ordering nonlaboratory tests such as the EEG, electrocardiogram (ECG), and neuroimaging.

Medical education often accustoms physicians to ordering tests, and psychiatrists are no exception. Laboratory testing, in particular, is routinely ordered before most psychiatric hospital admissions or transfers, for example. Yet, the result of any test should have the potential to alter patient management. If the test results will not alter management, then the test is unlikely to be relevant to the patient's current care. Despite increasing pressure to deliver cost-effective care, many clinicians still order a large number of screening laboratory and other studies. In reality, ordering "routine" screening laboratory tests very rarely detect abnormalities of any clinical significance. At the same time, in the outpatient setting, testing may not be ordered as frequently as indicated, especially for patients without closer medical outpatient follow-up.

At the time of admission to an inpatient unit, the lack of consensus regarding optimal patient workup may contribute to a tendency to order unnecessary laboratory tests. Aside from underserved populations, there is little evidence that broad laboratory tests improve patient care. Rather, choosing tests based on clinical hypotheses derived from a particular patient's clinical data, thereby minimizing the ordering of unnecessary studies and tests, constitutes a more reasonable approach. Such an approach often uses a narrow selection of routine screening tests. Subsequently, clinicians order nonroutine, additional tests as necessary based on the results of screening tests or particular findings on history or examination. The best screening evaluation includes a good history and physical examination, including a neurologic examination and mental status examination.

Psychiatrists use diagnostic testing to identify possible medical or neurologic illnesses that may cause or contribute to a patient's clinical presentation. Such testing occurs within the context of the history of the present illness, the physical examination, and the review of systems. Other tests are specific to psychiatry. For example, the measurement of blood levels of psychotropic medications can be useful to determine the adequacy of dosing or to monitor compliance. In addition, many tests, such as liver function tests (LFTs), white blood cell (WBC) count, and serum glucose, are performed to monitor the consequences of treatment of psychiatric illness. Laboratory detection of substances of abuse is helpful to identify patients who abuse illicit substances. For patients known to abuse substances, additional testing may be performed to assess the consequences of a patient's substance abuse.

In an outpatient setting, the clinical workup may differ because patients generally present with less acute symptoms and are less likely to have emergent conditions. Generally, a physical examination is impractical in the outpatient setting and, if needed, is often obtained through a patient's primary care provider. Patients who present for outpatient psychiatric care may or may not need initial laboratory testing, but if they do, focused testing should be performed based on suspected intersecting conditions. Neuroimaging studies may be underutilized in the outpatient psychiatric setting but should be ordered through specialist care if it is not possible for a psychiatrist to order them directly.

Many medical illnesses produce psychiatric symptoms or mimic psychiatric illness. Presentations with delirium, anxiety, depression, and hallucinations are nonspecific. Other medical and neurologic causes must first be excluded to be certain that a patient's symptoms are due to a mental illness. This assessment is not performed in a vacuum but occurs in the context of the patient's medical history and physical examination, and laboratory studies supplement the history and examination. The goal of the assessment is to identify causative factors that contribute to the patient's current symptoms. When psychiatric symptoms are found to be due to a general medical condition, initial efforts are focused on the treatment of the underlying condition. For many patients, treatment of the underlying medical condition results in a resolution of psychiatric symptoms. In addition, the diagnostic criteria for many psychiatric conditions, as listed in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), exclude symptoms attributable to a general medical condition or substance abuse.

Aside from using laboratory testing for diagnostic purposes, psychiatrists increasingly use laboratory testing to establish that administration of a particular treatment is safe, both before its initiation and to monitor ongoing adverse effects. For example, baseline laboratory studies may be obtained before the initiation of particular psychotropic medications. Testing also may be used to monitor compliance, measure therapeutic concentrations, and assess toxicity. Many psychotropic medications may have significant effects on physical health. Consequently, a psychiatrist may perform a pretreatment assessment of a patient's general health before initiating treatment. This assessment commonly includes a variety of laboratory tests.

Finally, there is continuing work toward biologic markers, or biomarkers, of major mental illnesses that will assist in the diagnosis and personalization of treatment. Unfortunately, research has not yet identified biomarkers that are ready for use in routine clinical practice.

PHYSICAL HEALTH MONITORING

Monitoring the physical health of psychiatric patients has two goals: To provide appropriate care for existing illnesses and to protect the patient's current health from possible future impairment. Disease prevention should begin with a clear concept of the condition to be avoided. Ideally, in psychiatry, this would focus on common conditions that could be a significant source of morbidity or mortality. It is clear that in psychiatry, a small number of clinical problems underlie a significant number of impairments and premature deaths.

Many psychiatric patients, especially in lower socioeconomic brackets, fail to receive periodic health maintenance examinations. Examinations and laboratory testing at the time of admission to a psychiatric hospital may be a rare opportunity to deliver preventive care. Preventive care can include monitoring for hypertension or providing counseling about healthy eating or smoking cessation.

Lifestyle-related health problems such as obesity, diabetes, hypertension, cardiovascular disease, and sexually transmitted diseases (STDs) are frequent comorbidities in some psychiatric populations. It is helpful to discuss proper nutrition, diet, and exercise as part of the prevention and management of excessive weight gain. The physician also should discuss information about preventable diseases that are more likely to occur in obese individuals and the role of monitoring fasting blood sugars and fasting lipid levels in disease prevention. Sexually transmitted infections are more common in young psychiatric patients than in the general population. In patients with risk factors for human immunodeficiency virus (HIV) infection, it is important to order screening tests for the virus (though screening may require a patient’s permission).

Illnesses such as cardiovascular disease are often associated with aging, but this is not necessarily the case in people with mental illness. For example, among patients with bipolar disorder, comorbid cardiovascular disease leads to greater mortality than suicide and occurs at a younger age than in nonmentally ill counterparts. Patients with risk factors for metabolic syndromes, such as obesity, should be screened for hypertension, dyslipidemia, and glucose levels. All patients who use tobacco should be counseled about smoking cessation with the goal of preventing coronary artery disease, stroke, and other medical comorbidities.

Detecting medical complications not only extends lifespan but also lessens the impact of mental illness and thereby improves quality of life. Treatment of medical conditions lessens the severity of symptoms of affective and psychotic disorders. Early treatment of medical conditions may reduce the likelihood of medical hospitalization, which leads to an increased risk of rehospitalization for self-harm and suicidal acts after discharge for patients with serious mental illness.

DIAGNOSTIC ASSESSMENT

This section reviews studies that may be useful in the diagnostic assessment of patients presenting with psychiatric complaints. Clinicians should perform an examination that is individualized to the specific needs of the patient. There is no consensus about standard laboratory tests for psychiatric patients, and standards of care differ between outpatient and inpatient settings.

In the outpatient setting, laboratory testing is relatively uncommon unless a medical illness is suspected of generating a psychiatric symptom or collection of symptoms. Such suspicions may be supported by a patient's history or physical finding and may indicate laboratory testing, neuroimaging, and follow-up by specialists to treat an underlying disorder. In certain situations, psychiatric care may be beneficial in symptomatic treatment alongside the primary treatment.

When patients are admitted to an inpatient psychiatric unit, many times "screening" laboratory studies are ordered, although there is no evidence that supports the role of laboratory studies in "medical clearance" for admission to psychiatric units. Certainly, such studies are indicated in patients who have a history or suspected history of conditions that may affect hepatic or renal function, but for younger, healthy patients, general laboratory studies do little to advance patient care. Rather, specific studies can be ordered as subsequent information is obtained.

For patients with a suspected or established history of alcohol use or hepatic impairment, LFTs including alanine aminotransferase (ALT) and aspartate aminotransferase (AST) to assess their ability to metabolize prescribed medication are helpful. Patients who have a history of lithium use or suspected renal impairment should have an assessment of renal function, including blood urea nitrogen (BUN) and creatinine (Cr), and a urinalysis to evaluate their capacity to excrete metabolized medication. In patients with a history of treatment-refractory depression or appropriate physical findings, thyroid-stimulating hormone (TSH) may be considered.

Role of History and Physical Examination

A thorough history, including a review of systems, is the basis for a comprehensive patient assessment. The history guides the clinician in the selection of laboratory studies that are relevant for a specific patient. Some psychiatric patients, because of the nature of their illnesses, are not capable of providing sufficiently detailed information. Collateral sources of information, including family members and prior clinicians and their medical records, may be particularly helpful in the assessment of such patients.

The history of present illness includes the chief complaint (or the reason the patient seeks or was brought for assistance), the nature of the current problems, and their current treatments. The past psychiatric history should include information about previous psychiatric problems and a history of prior treatments. It should contain the medications used to treat the patient, the doses prescribed, and the durations of each medication trial. The past psychiatric history should also contain documentation of dates and locations of past psychiatric admissions, the reason for admission, and the treatments provided. If the patient reports an allergy to a specific medication, then the nature of the allergic response should be noted.

The patient’s medical history is an important component of the history. It should include notation of prior injuries and, in particular, head injuries that resulted in the loss of consciousness and other causes of unconsciousness. The patient’s medical history also should note pain conditions, ongoing medical problems, prior hospitalizations, prior surgeries, and a list of the patient’s current medications. Toxic exposures are another important component of medical history. Such exposures are often workplace related.

The social history contains many of the details relevant to the assessment of character pathology, including risk factors for personality disorders, as well as information relevant to the assessment of other psychiatric disorders. Commonly, the social history includes legal history, information about family and other significant relationships, and educational and occupational history. The clinician should take a thorough history of alcohol and substance use. History of the use of substances, illicit and prescribed, should contain information regarding the timing of the initiation of use, the frequency of use, the quantity used, and the date of most recent use for each substance. A thorough review of symptoms should be performed. Unrecognized medical conditions are often detected during the review of systems.

The frequency with which psychiatrists perform physical examinations on their patients is highly variable; it is common for other physicians to perform the physical examination in acute settings before or after the psychiatrist obtains the history. Under certain clinical scenarios, it may be appropriate to postpone the physical examination, such as when a patient is agitated or aggressive. Such deferments should be for as brief a time as possible. As a general rule, it is wise to have a chaperone present during the physical examination.

Physical examinations may provide data helpful in the diagnosis and management of substance abuse. For example, intravenous (IV) drug use may be identified by the presence of “track” marks—small scars following the outline of a vein produced from repeated injections. In chronic users, track marks may be less apparent and hyperpigmented, fibrotic, depressed, round papules on the forearms or legs may be apparent from “skin popping” (subcutaneous injection). Perforation of the nasal septum or chronic nosebleeds may occur following chronic insufflation of cocaine. Opioid intoxication is associated with sedation, dysarthria, slowed cognition, and pinpoint pupils. In contrast, withdrawal from opiates is associated with lacrimation, rhinorrhea, yawning, piloerection, myalgias, pupillary dilation (mydriasis), and bowel discomfort. These symptoms occur 1 to 2 days following discontinuation of methadone and 6 to 12 hours after stopping shorter-acting opiates. Alcohol or sedative-hypnotic withdrawal is associated with autonomic hyperactivity, nausea, tremulousness, diaphoresis, headache, anxiety, and agitation, as well as perceptual disturbances and clouding of sensorium in severe cases.

When evaluating patients with cognitive impairment, the physical examination may also provide etiologic clues when accompanying neurologic signs are identified, such as cogwheel rigidity and tremor associated with Parkinson disease or neurologic deficits suggestive of prior strokes. Standard laboratory studies commonly assessed in patients with neurocognitive disorders include a complete blood count (CBC), serum electrolytes, LFTs, BUN, Cr, thyroid function tests, serum $B_{12,}$ and folate levels Venereal Disease Research Laboratory (VDRL) test, and a urinalysis. Structural neuroimaging studies are often performed, particularly if there are focal neurologic findings. EEG and/or cerebrospinal fluid (CSF) evaluation may be performed in some cases if seizures, central nervous system (CNS) infection, and/or other etiologies requiring such evaluations are suspected. When patients are delirious, the neurologic examination may be complicated by inattention and/or altered level of consciousness. Delirium workup may include a similar laboratory workup, but the appropriate evaluation for a particular delirious patient depends upon historical and clinical features. Urine or blood cultures, chest radiograph, arterial blood gases, chemistry panel, endocrine evaluation, neuroimaging studies, or EEG may be appropriate, among other studies.

As is true for most presenting symptoms, the evaluation of neuropsychiatric symptoms requires consideration of a broad differential diagnosis; the differential diagnosis for a neuropsychiatric presentation may include primary psychiatric disorders, neurologic disorders, or other medical conditions. An important part of the medical and laboratory assessment of psychiatric symptoms is to determine which medical conditions to include in the differential diagnosis based upon the patient's history and examination findings. Further, comorbid medical conditions may complicate the management of psychiatric patients, and laboratory evaluation for a variety of conditions may be important in the course of clinical care, often in collaboration with other specialists.

Serum Electrolyte Evaluation

Serum electrolyte levels may be useful in the initial evaluation of a psychiatric patient, especially if he or she appears obtunded or cognitively slowed for unclear reasons. Older adults who exhibit a more rapid onset of decreased cognitive function or depression may have electrolyte abnormalities. Abnormalities also may occur in response to the administration of psychotropic medications.

Hypokalemia may be present in eating disorder patients who purge or abuse laxatives and in psychogenic vomiting. Diuretic abuse by eating disorder patients also may produce hypokalemia. Low levels of potassium are associated with weakness and fatigue. Characteristic ECG changes occur with hypokalemia and consist of cardiac arrhythmias, U waves, flattened T waves, and ST-segment depression.

Eating disorder patients with anorexia nervosa or bulimia nervosa usually receive a fairly standard set of laboratory studies, including serum electrolytes (particularly potassium and phosphorus), blood glucose, thyroid function tests, liver enzymes, total protein, serum albumin, BUN, Cr, CBC, and ECG. Serum amylase is often assessed in bulimic patients.

Magnesium levels may be low in patients with alcohol use disorders or malnutrition. Low magnesium levels are associated with agitation, confusion, and delirium. If untreated, then convulsions and coma may follow. Additionally, hypomagnesemia increases the risk for arrhythmias such as torsade de pointes.

Low levels of serum phosphorus may be present in eating disorder patients with purging behavior. Phosphorus levels may also be low in anxiety patients who hyperventilate. Hyperparathyroidism may produce low serum phosphorus levels. Elevated serum phosphorus levels are seen in hypoparathyroidism.

Hyponatremia is seen in psychogenic polydipsia and SIADH and in response to certain medications, such as oxcarbazepine and carbamazepine. In older adults, low sodium levels may result from physiologic or dietary alterations and be associated with cognitive slowing or delirium and could be mistaken for dementia or depression. Low serum chloride levels may occur in eating disorder patients who purge by self-induced vomiting.

Serum calcium abnormalities are associated with a variety of behavioral abnormalities. Low serum calcium levels are associated with depression, delirium, and irritability. Elevated levels are associated with depression, psychosis, and weakness. Laxative abuse, common in anorexia binge–purge type, can be associated with hypocalcemia. Hypocalcemia secondary to hypoparathyroidism may occur in patients who have undergone surgery for thyroid disease. Hypercalcemia can be seen in association with hyperparathyroidism, which is sometimes a side effect of treatment with lithium.

Renal Function

Tests of renal function, including BUN and Cr, are serum markers used to estimate glomerular filtration rate (GFR). Other relevant laboratory studies include routine urinalysis and Cr clearance. Renal failure may result in lethargy or delirium. BUN is commonly elevated with dehydration. Cr is the serum marker most useful in clinically estimating GFR.

Routine urinalysis is a common screening test that includes an examination of the general appearance of the sample and measurement of the pH, urine-specific gravity, urine bilirubin, and urine glucose. Elevations in urine glucose can be seen in diabetes. Elevated urine bilirubin occurs in biliary disease. A high urine-specific gravity may occur in diabetes mellitus, in dehydrated states, or from SIADH. A low urine-specific gravity may occur in diabetes insipidus (DI) or from excessive water ingestion. In older adults, sudden changes in behavior or cognition may portend an underlying urinary tract infection, and urinalysis is generally warranted.

Elevated levels of porphobilinogen are found in the urine of symptomatic patients with acute intermittent porphyria. Symptoms of this disease include psychosis, apathy, or depression, along with intermittent abdominal pain, neuropathy, and autonomic dysfunction. If urine porphobilinogen levels are elevated when the patient is symptomatic, then a collection of a 24-hour urine specimen for quantitative assessment of porphobilinogen and aminolevulinic acid is indicated.

Liver Function

LFTs commonly include the serum aminotransferases, alkaline phosphatase, γ-glutamyl transpeptidase, serum bilirubin, and tests of synthetic function, usually the serum albumin concentration and prothrombin time.

Elevations in AST may occur with diseases of the liver, heart, lungs, kidneys, and skeletal muscle. In patients with alcohol-induced liver disease, AST is typically more elevated than ALT. In viral- and drug-induced liver disease, ALT is often elevated. Serum GGT is elevated in hepatobiliary disease, including alcohol-induced liver disease and cirrhosis. Various psychotropic medications, including valproate, may induce transient transaminitis. Dosage of second-generation antipsychotics and some antidepressants must be reduced in patients with impaired hepatic function.

Alkaline phosphatase elevations occur in many diseases, including diseases of the liver, bone, kidney, and thyroid. Levels of alkaline phosphatase may be elevated in response to some psychiatric medications, most notably the phenothiazines.

Serum ammonia levels are often elevated in patients with hepatic encephalopathy. High levels are associated with the delirium of hepatic encephalopathy. Serum ammonia levels also may be elevated in patients undergoing treatment with valproate.

Serum bilirubin is an index of hepatic and bile duct function. Prehepatic, unconjugated, or indirect bilirubin and posthepatic, conjugated, or direct bilirubin are often assessed to help elucidate the origin of the elevation in bilirubin.

The total protein is the measurement of serum albumin and globulins. Many psychiatric medications are protein bound. Low levels of serum total protein result in a high fraction of an ingested drug remaining in the unbound (active) state. High levels of unbound drug increase the active effects and side effects that a patient experiences. Total protein may be low in malnourished states, such as those seen in eating disorder patients. Low total protein and serum albumin in a patient with elevated liver enzymes is an indicator of significant liver disease. Consequently, these levels are often assessed in patients who abuse alcohol.

A relatively higher elevation in serum aminotransferases compared to alkaline phosphatase suggests hepatocellular injury. The opposite pattern is seen with cholestasis. Low albumin levels are seen in chronic conditions such as cirrhosis. Alcoholic liver disease is suggested when the ratio of AST to ALT is 2:1 or greater, although this may occur with steatohepatitis or hepatitis-C–related cirrhosis. When the AST to ALT ratio is 2:1, or greater and the GGT is twice the normal level, the pattern strongly suggests alcoholic liver disease.

Infectious Disease

The diagnostic assessment for patients with psychiatric symptoms may include a workup for infectious illness, depending upon the patient's history and examination findings. Further, comorbid infections requiring clinical attention and referral may be present in psychiatric patients with high-risk behaviors such as IV substance use or high-risk sexual behavior. Below, infectious disease as a differential diagnosis in psychiatric presentations is reviewed. Additionally, infectious diseases that may be a focus of clinical attention in patients with established psychiatric illness are also discussed.

A 49-year-old homeless male with a history of bipolar I disorder was brought by ambulance to the emergency department after a witnessed seizure. He had a fever of 39 °C, and his heart rate was in the 120s. He was severely disorganized and agitated, with unintelligible speech, and appeared to be responding to internal stimuli. He was unable to cooperate with a neurologic examination. Magnetic resonance imaging (MRI) of the head demonstrated T2/FLAIR hyperintensity involving the temporal lobe. Cerebrospinal fluid (CSF) examination revealed an elevated WBC of 121 cells/μL (mostly lymphocytes) and mild protein elevation (57 mg/dL). Herpes simplex virus (HSV) was identified in CSF. Following antiviral treatment for herpes encephalitis, the patient recovered to his baseline.

In this patient's case, despite known bipolar I disorder and severe psychiatric symptoms at the time of presentation, there were indicators of a comorbid medical illness, including seizure, aphasia, and fever. An evaluation for infectious etiologies was required in order to initiate the correct treatment for his condition.

Central Nervous System Infection. Infections of the CNS often present with neuropsychiatric symptoms. These symptoms may range from confusion, inattention, or altered level of consciousness, to severe agitation and psychosis. CNS infection with herpes simplex virus (HSV) is particularly notorious for causing psychiatric disturbances. Similarly, tertiary syphilis can have a number of psychiatric and neurologic manifestations. Other CNS infections may also cause psychiatric symptoms; delirium is especially common. It is unusual for CNS infections to cause neuropsychiatric symptoms in the absence of signs such as fever, nuchal rigidity, seizure, or other neurologic findings. However, there are exceptions, and it is important to know the immune status of a patient. Infected patients who are immunocompromised may be less likely to mount a fever; mental status changes among the immunocompromised host should alert clinicians to a broad differential that includes a variety of infections. Various infectious agents can infect the CNS, including bacteria, viruses, prions, fungi, and parasites. The workup initiated depends upon many factors, including the patient's travel history, occupational and recreational exposures, sexual behaviors, and immune status, all of which may put the patient at risk for particular infections.

A 58-year-old man with schizoaffective disorder, treated with stable doses of haloperidol, clozapine, and lithium, presented to the emergency department with his conservator for evaluation of fever and altered mental status. On evaluation, he was febrile, tachycardic, rigid, and tremulous. Neuroleptic malignant syndrome (NMS) was suspected, and psychotropic medications were discontinued. MRI was unremarkable, but CSF revealed elevated WBC of 54 cells/μL (mostly lymphocytes), elevated protein of 71 mg/dL, and positive serology for West Nile virus. With supportive care and eventual reinitiation of his psychotropic medication regimen, he eventually recovered to baseline, but not without first requiring psychiatric hospitalization for relapse of manic and psychotic symptoms.

Other Infections. In addition to CNS infection, a systemic infection may cause mental status changes. For most patients presenting with delirium, an infection should be included in the differential diagnosis. Patients with sepsis or septic shock commonly develop delirium. For vulnerable patients such as the older adults or cognitively impaired, an infection as mild as cystitis may be sufficient to induce mental status changes. An infectious workup for delirium generally includes a CBC, urinalysis, chest x-ray, and sometimes blood cultures, among other specific evaluations depending upon the individual patient.

In addition to considering infectious disease in the differential diagnosis when appropriate clinical and historical features are present, evaluation for certain infectious diseases is sometimes indicated in psychiatric patients with known risk factors. Below, specific infectious agents that may be relevant in patients with high-risk sexual behavior or IV substance use are discussed. Some evaluations such as HIV screening may be offered in the course of routine clinical care, regardless of patient risk factors; CDC guidelines now recommend opt-out HIV screening for all adolescents and adults and annual HIV screening for patients at high risk for HIV infection.

Intravenous Drug Use and Infection. The IV route is used for many substances of abuse. Most commonly, heroin, amphetamines, and cocaine are used alone or in combination. Because needles may be contaminated, IV drug users are at risk for bacterial endocarditis, hepatitis

B and C, and HIV infection. It has been estimated that over 60% of new cases of hepatitis C occur in individuals with a history of injecting illicit drugs.

The use of contaminated needles or nonsterile injection sites places IV drug users at risk for bacterial infections, including abscesses, bacteremia, and bacterial endocarditis. Findings on physical examination suggestive of endocarditis, possible bacteremia, or abscess necessitate obtaining a CBC to rule out an elevated WBC. Blood cultures should be obtained if the patient is febrile or if findings are suggestive of bacteremia or endocarditis, and internal medicine consultation should be obtained.

Sexually Transmitted Diseases. Some psychiatric illnesses, such as mania and substance abuse, are associated with a higher risk of contracting STDs. STDs include HSV types 1 and 2, Chlamydia, hepatitis B and C viruses, gonorrhea, syphilis, and HIV. Risk factors for STD include contact with sex workers, drug abuse, prior history of STDs, meeting sex partners on the Internet, multiple sex partners, a new sex partner, and being young or unmarried.

Many patients require supportive counseling before and after STD testing. Counseling consists of providing patients with educational material, allowing patients the opportunity to ask questions, and assessing their emotional response to the process. Inquiring about a patient’s motivation for testing often is a helpful way to initiate discussion of other issues. Patients should be informed about the meaning of positive and negative results. Patients who test positive may require referral to a specialist who can discuss the implications of the result and future treatment. Patients with high-risk behaviors and negative test results should be cautioned about the length of time required for seroconversion with HIV testing and the need, when appropriate, for supplemental testing. It is useful to evaluate the patient’s understanding of ways to reduce the risk of contracting or transmitting STDs. Regardless of their test results, all patients can benefit from a discussion of high-risk behaviors. For patients who test positive, in addition to treatment, it is particularly important for clinicians to provide the patient with information about how to minimize the risk of STD transmission. Clinicians should emphasize the need for protected sex with fully informed partners and the avoidance of donating sperm, blood, or organs. Clinicians should warn patients about the risks of transmitting certain STDs associated with sharing razors, toothbrushes, and any other objects that could have blood on them.

Chlamydia. Chlamydia infection can cause pelvic inflammatory disease, ectopic pregnancy, chronic pelvic pain, and infertility. It is also associated with an increased risk of contracting and transmitting HIV. Reinfection is common and is usually due to a lack of partner treatment. Many infections are asymptomatic. Chlamydia screening uses tests based on nucleic acid amplification (NAA). These amplification tests have high sensitivity and specificity for men and women, using urine or cervical or urethral swabs.

Gonorrhea. Gonorrhea infection can cause pelvic inflammatory disease, ectopic pregnancy, chronic pelvic pain, and infertility. It is also associated with an increased risk of contracting and transmitting HIV. Reinfection is common and is usually due to a lack of partner treatment. Many infections are asymptomatic. The diagnosis of a gonococcal infection can be made with NAA techniques, deoxyribonucleic acid (DNA) probes, Gram stain, or culture on Thayer–Martin media. NAA tests have high sensitivity and specificity for men and women, using urine or cervical, vaginal, or urethral swabs. In women, vaginal or cervical swabs have higher sensitivity than urine samples.

Human Immunodeficiency Virus (HIV). The enzyme-linked immunosorbent assay (ELISA) test and the Western blot test are used in the assessment of a patient’s HIV status. Both tests detect the presence of antibodies to HIV. Antibodies to HIV become detectable anywhere from 3 weeks to 3 months after infection. Typically, the ELISA test is used as a screening test, and the Western blot test is used to confirm the result. Other tests are performed to assess the extent of HIV disease burden, treatment response to antiretroviral therapy, and the degree to which the virus has affected the immune system. Measurement of viral load is used to assess the HIV disease burden. Measurement of $CD4^+$ T cell count provides information about the need for prophylaxis against opportunistic infections.

The Centers for Disease Control and Prevention recommend HIV screening for all adolescent and adult patients. Additionally, annual HIV testing is recommended in high-risk populations. High-risk groups include men who have sex with men, individuals who exchange sex for money or substances, IV drug users, individuals who have had sex with one or more partners since their last HIV test, and individuals who have had sex with an HIV-infected person or anyone in the aforementioned high-risk groups. HIV is transmitted via blood and certain body fluids (semen, rectal fluids, vaginal fluids, breast milk) when these fluids come into direct contact with mucous membranes, damaged tissues, or when injected directly into the bloodstream.

Psychiatric and behavioral symptoms associated with HIV vary according to whether patients are in the acute or chronic stage of infection. In the acute stage, HIV may present with headache and malaise, whereas HIV-infected patients may have CNS manifestations as their predominant symptoms even when other symptoms are absent. Behavioral changes in an individual patient may be due to either the direct effect of the virus on the brain or associated conditions such as infection, mass effect, or malnutrition. CNS manifestations of HIV infection include dementia, personality changes, affective symptoms of either mania or depression, and psychosis. HIV infection may be associated with delirium, dementia, mania, and atypical presentations of anxiety, schizophrenia, and depression.

With antiretroviral therapies, HIV-associated dementia is less common today, but milder HIV-associated neurocognitive disorders (HAND) remain prevalent, with approximately half of HIV-infected individuals demonstrating a lower level of cognitive performance than would be predicted when compared to population norms. Depression occurs in up to 58% of people living with HIV. Mania associated with HIV or AIDS also may occur either in the acute infection or in the context of HIV-related dementia.

Syphilis. Nontreponemal tests for syphilis, such as the rapid plasma reagin (RPR) test and the VDRL test, are common screening tests for syphilis. Quantification testing may be performed after a positive RPR or VDRL test. Quantification enables levels to be followed to assess response to treatment. After a positive nontreponemal screening test, a more specific treponemal test, such as the fluorescent treponemal antibody absorption (FTA-ABS) test, is used to confirm the positive result. The FTA-ABS test detects antibodies against *Treponema pallidum* spirochetes. Once positive, even with adequate treatment, specific treponemal tests like the FTA-ABS may remain positive for years. False-positive results may occur; this is true for both treponemal and nontreponemal tests. Pregnant patients may screen falsely positive for syphilis. False-positive nontreponemal tests are also associated with acute febrile illnesses, and sometimes in patients with chronic conditions, especially patients with systemic lupus erythematosus (SLE).

When syphilis infection of the CNS is suspected, a VDRL is performed on CSF. Patients with neurosyphilis also commonly have abnormalities in protein levels, γ-globulins, and cell counts in CSF. Due to the low sensitivity of the VDRL, the FTA-ABS test may also be used to evaluate CSF when neurosyphilis is suspected. It has higher sensitivity but lower specificity.

Viral Hepatitis. Several types of viruses may cause viral hepatitis. Viral hepatitis produces abnormalities in LFTs, including elevation of liver enzymes. Symptoms range from mild flu-like manifestations to rapidly progressive and fatal liver failure. Psychiatric manifestations include depression, anxiety, weakness, and psychosis. Viral hepatitis also may impair the metabolism of psychotropic medications that are metabolized by the liver. Impaired liver metabolism requires an adjustment of the dose of medications metabolized by the liver or consideration of agents that are less affected by alterations in liver metabolism. Viruses causing hepatitis include hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), and hepatitis E virus (HEV). HAV and HEV are usually transmitted via the fecal–oral route. HBV and HCV are transmitted via contamination by body fluids; this may include transmission by contact with infected blood or blood products or by sexual contact. HDV is a defective RNA (ribonucleic acid) virus that causes hepatitis only in association with HBV infection.

The WBC is usually normal to low in patients with hepatitis, especially in the preicteric phase. Large atypical lymphocytes occasionally are present. Rarely, aplastic anemia follows an episode of acute hepatitis not caused by any of the known hepatitis viruses. Mild proteinuria is common, and bilirubinuria often precedes the appearance of jaundice. Acholic stools frequently are present during the icteric phase. Strikingly elevated AST or ALT occurs early, followed by elevations of bilirubin and alkaline phosphatase. In a minority of patients, elevations of bilirubin and alkaline phosphatase persist after aminotransferase levels have normalized. Cholestasis may be substantial in acute HAV infection. Marked prolongation of the PT in severe hepatitis correlates with increased mortality.

Chronic hepatitis, characterized by elevated aminotransferase levels for more than 6 months, develops in less than 5% of immunocompetent adults with acute HBV infection. Fifty percent to 85% of all persons with acute HCV infection develop chronic HCV infection. Ultimately, cirrhosis develops in as many as 50% of those with chronic HCV infection and 20% of those with chronic HBV infection; the risk of cirrhosis is even higher in patients coinfected with both viruses or with HIV. Patients with cirrhosis are at risk, with a rate of 0% to 3% per year, of hepatocellular carcinoma. Even in the absence of cirrhosis, patients with chronic HBV infection—particularly those with active viral replication—are at an increased risk.

HEPATITIS B VIRUS. Psychiatric manifestations have been reported during all stages of HBV infection. HBV is transmitted via contamination by body fluids and is usually transmitted by contact with infected blood or blood products, by sexual contact, or from mother to baby at birth. The virus is present in saliva, semen, and vaginal secretions, as well as blood. The incubation period of HBV is 1 to 4 months. Transmission of HBV commonly occurs during sexual contact and via the use of shared implements for IV drug use; it also may occur through tattooing and piercing and as a result of needle-stick injuries. After acute HBV infection, HBV infection persists in 1% to 2% of immunocompetent adults. Persons with chronic HBV infection are at substantial risk of cirrhosis and hepatocellular carcinoma. There is common comorbidity between HBV infection and HIV infection, given the shared risk factors for both conditions.

HBV infection can be detected by measuring viral antigens, antibodies to the virus, and viral DNA. The appearance of HBsAg is the first evidence of infection and persists throughout the clinical illness. The detection of HBsAg establishes active infection with HBV and implies infectivity. When it is present beyond 6 months, infection is considered chronic. Hepatitis B e antigen (HBeAg) is a soluble protein found only in HBsAg-positive serum. HBeAg indicates viral replication and infectivity. Antibody to HBsAg (anti-HBs) appears after clearance of HBsAg and after successful vaccination against hepatitis B. Disappearance of HBsAg and the appearance of anti-HBs signal recovery from HBV infection, noninfectivity, and immunity. Detection of the hepatitis B surface antigen (HBsAg) indicates active or chronic infection. IgM antibody to HBcAg (anti-HBc) in the setting of acute hepatitis indicates a diagnosis of acute HBV infection. It fills the serologic gap in patients who have cleared HBsAg but do not yet have detectable anti-HBs. IgG anti-HBc also appears during acute HBV infection but persists indefinitely, whether the patient recovers or develops chronic hepatitis.

HEPATITIS C VIRUS. HCV infection is often diagnosed in individuals who abuse IV drugs, as these individuals are at high risk for contracting HCV infection via the use of contaminated equipment. Clinical illness is generally mild, usually asymptomatic; it is characterized by waxing and waning aminotransferase elevations and a high rate (50% to 85%) of chronic HCV infection. HCV infection is associated with an increased risk of cirrhosis and hepatocellular carcinoma. Diagnosis of HCV infection is based on immunoassays that detect antibodies to HCV (anti-HCV). These tests are complemented by assays for HCV RNA to confirm active versus past infection. Fortunately, antiviral treatments have up to a 95% success rate in the treatment of HCV after infection.

Endocrine Evaluation

Endocrine disease is of great relevance to psychiatry. Endocrine illness frequently has psychiatric manifestations. Management of psychiatric illness may be complicated by comorbid endocrine disease. For these reasons, screening for endocrine disease often is of relevance to the psychiatrist.

Adrenal Disease. Adrenal disease may have psychiatric manifestations, including depression, anxiety, mania, dementia, psychosis, and delirium. However, patients with adrenal disease rarely come to the attention of psychiatrists. Assessment and management of these patients are best done in conjunction with specialists.

Low plasma levels of cortisol are found in Addison disease. These patients may have symptoms that are also common in psychiatric conditions, including fatigue, anorexia, weight loss, and malaise. Patients may also have memory impairment, confusion, or delirium. Depression or psychosis with hallucinations and delusions may occur.

Elevated levels of cortisol are seen in Cushing syndrome. About half of all patients with Cushing syndrome develop psychiatric symptoms. These symptoms may include lability, irritability, anxiety, panic attacks, depressed mood, euphoria, mania, or paranoia. Cognitive dysfunction may include cognitive slowing and poor short-term memory. Symptoms usually improve when cortisol normalizes. If not, or if symptoms are severe, then psychiatric treatment may be necessary.

Cortisol levels have not been found to be useful in the assessment or management of a primary psychiatric disease. In particular, the dexamethasone-suppression test (DST) remains a research tool in psychiatry that is not used in routine clinical care.

Anabolic Steroid Use. The use of anabolic steroids has been associated with irritability, aggression, depression, and psychosis. Some athletes and bodybuilders may abuse anabolic steroids, but they are also increasingly used to enhance sexual performance, even in older adults. It is important to inquire about steroid use given the availability, even if a patient does not appear to have excess muscular bulk. Urine specimens can be used to screen for these agents. Because so many compounds have been synthesized, a variety of tests may be required to confirm the diagnosis, depending upon the compound that has been used. Consultation with a specialist is advised.

Generally, androgens other than testosterone can be detected by gas chromatography and mass spectroscopy. Exogenous testosterone is indistinguishable from endogenous testosterone. When the use of exogenous testosterone is suspected, the urinary ratio of testosterone to its endogenous epimer, epitestosterone, is assessed. Usually, the ratio ranges from 1:1 to 3:1. When exogenous use occurs, the ratio may be greater than 4:1 and even greater than 6:1. Another method for detection of exogenous testosterone use is to evaluate the ratio of ^{13}C to ^{12}C in urinary metabolites of testosterone. Because synthetic testosterone preparations are derived from plant sterols, their presence, in comparison to the presence of endogenous testosterone alone, produces a lower ratio of ^{13}C to ^{12}C.

Antidiuretic Hormone. Arginine vasopressin (AVP), also called antidiuretic hormone (ADH), is decreased in central DI. DI may be central (due to the pituitary or hypothalamus) or nephrogenic. Nephrogenic DI may be acquired or due to an inherited X-linked condition. Lithium-induced DI is an example of an acquired form of DI. Lithium has been shown to decrease the sensitivity of renal tubules to AVP. Patients with central DI respond to the administration of vasopressin with a decrease in urine output. Secondary central DI may develop in response to head trauma that produces damage in the pituitary or hypothalamus.

About one-fifth of patients taking lithium develop polyuria, and a larger amount may have some degree of impairment in concentrating urine. Chronic treatment with lithium is a common cause of nephrogenic DI. However, there are other causes of polyuria in lithium-treated patients in addition to nephrogenic DI. Primary polydipsia is common and is often associated with the dry mouth associated with many psychiatric medications. When patients chronically treated with lithium develop altered mental status, they may become functionally fluid restricted due to inability to drink to thirst (often with polydipsia and polyuria at baseline). Close monitoring of fluid intake and urine output is required; patients are at high risk of developing hypernatremia and severe dehydration if they have impaired ability to drink to thirst, combined with impaired ability to concentrate urine.

A 73-year-old gentleman with bipolar I disorder had been stably managed on lithium for over 40 years. He presented to the hospital with altered mental status. Pneumonia was diagnosed, and the patient ultimately required intubation due to respiratory distress. While intubated, he developed hypernatremia and acute renal failure (prerenal). A review of his fluid intake and output revealed that he'd had several liters of daily urine output but was not receiving adequate fluid replacement. Following nephrology evaluation of serum and urine osmolality studies, DI was diagnosed. IV fluids were increased and adjusted to provide free water replacement.

Excessive secretion of AVP increases the retention of fluid in the body. This condition is called *SIADH.* Water retention in SIADH causes hyponatremia. SIADH may develop in response to injury to the brain or from medication administration (including phenothiazines, butyrophenones, carbamazepine, oxcarbazepine, as well as SSRIs and many other agents). The hyponatremia associated with this condition may produce delirium. The relationship between AVP and psychogenic polydipsia remains unclear. However, it appears that in a minority of cases with psychogenic polydipsia, AVP levels may be abnormal. SIADH is associated with hyponatremia, low serum osmolality, and high urine osmolality. It should be considered when patients demonstrate hyponatremia and concentrated urine (i.e., high urine osmolality or high specific gravity). This condition should be investigated with the assistance of a specialist.

Human Chorionic Gonadotropin. Human chorionic gonadotropin (hCG) can be assessed in the urine and blood. The urine test for hCG is the basis for the commonly used urine pregnancy test. Routine tests are most accurate when performed 1 to 2 weeks after a missed period. However, there are ultrasensitive urine hCG tests that can accurately detect pregnancy seven days after fertilization. Pregnancy tests often are obtained before initiating certain psychotropic medications, such as carbamazepine and valproic acid, which are associated with congenital anomalies.

Parathyroid Hormone. Parathyroid hormone modulates serum concentrations of calcium and phosphorus. Dysregulation in this hormone and the resulting production of abnormalities in calcium and phosphorus may produce depression or delirium. Chronic lithium treatment may result in hyperparathyroidism and hypercalcemia in a small percentage of patients.

Neuropsychiatric symptoms associated with hyperparathyroidism and hypercalcemia include depression, anxiety, cognitive dulling, lethargy, and psychosis; delirium and stupor may occur as calcium levels rise. Symptoms usually improve with treatment of the underlying condition.

Prolactin. Prolactin levels may become elevated in response to the administration of antipsychotic agents (high potency first-generation and some second-generation) that block dopamine receptors in the pituitary. Dopamine inhibits the release of prolactin; thus, dopamine blockade leads to an increase in prolactin release.

Elevated prolactin levels in premenopausal women are associated with menstrual abnormalities, infertility, alterations in libido, decreased bone density, and galactorrhea. Most premenopausal women who have hyperprolactinemia do not have galactorrhea. Generally, levels greater than 100 ng/mL are associated with infertility and amenorrhea, hot flashes, and vaginal dryness. Levels from 50 to 100 ng/mL may cause amenorrhea or oligomenorrhea. Values of 20 to 50 ng/mL may cause infertility even when there is no abnormality of the menstrual cycle. The normal range for serum prolactin is from 5 to 20 ng/mL.

In men, hyperprolactinemia may result in decreased libido, erectile dysfunction, fatigue, gynecomastia, and infertility. Only rarely does galactorrhea occur. Chronic hyperprolactinemia may result in loss of body hair, loss of muscle mass, and osteoporosis.

Cerebral magnetic resonance imaging (MRI) is not usually performed if the patient is taking an antipsychotic drug known to cause hyperprolactinemia and the magnitude of the prolactin elevation is consistent with drug-induced causes.

Prolactin levels may briefly rise after a seizure. For this reason, prompt measurement of a prolactin level after possible seizure activity may assist in differentiating a seizure from a nonepileptic behavioral spell.

Thyroid Hormone. Disease of the thyroid is associated with many psychiatric manifestations. Thyroid disease is most commonly associated with depression and anxiety but may also give rise to symptoms of panic, dementia, and psychosis. Thyroid studies are often evaluated in patients with depression, as thyroid disease may mimic depression. It is difficult to achieve euthymia if a patient is not euthyroid.

Measurements of TSH typically are used as a screening test for thyroid disease. If normal, then no further assessment is performed. If high, then TSH may be repeated and free T4 added to assess the degree of hypothyroidism. If serum TSH is low, then free T4 and T3 are assessed to determine the degree of hyperthyroidism. Hypothyroidism is characterized by an elevated TSH and a low free T4. Subclinical hypothyroidism consists of a high TSH and a normal free T4. Hyperthyroidism consists of low TSH and high free T4 and T3.

Usually, thyroid function is assessed in psychiatric patients with a history of thyroid disease or those with symptoms suggestive of thyroid illness. Such symptoms may include increased appetite, weight loss, and heat intolerance in hyperthyroidism or weight gain, fatigue, and cold intolerance in hypothyroidism. Alternatively, risk factors for thyroid disease may prompt examination of thyroid function. Risk factors include prior treatment with lithium or iodine-131, a history of irradiation of the neck and chest, or a history of thyroidectomy. Additionally, thyroid function is commonly assessed in patients currently receiving exogenous thyroid hormone replacement to ensure that they are euthyroid.

Interpretation of thyroid function tests may be complex and is often best done with the assistance of a specialist. Interpretation is further complicated by the presence of transient abnormalities of thyroid function in many newly admitted psychiatric patients. These abnormalities normalize over time without treatment and may be related to stress.

Pancreatic Function. The pancreas is both an exocrine and endocrine gland. The endocrine function of the pancreas is to control blood sugar levels through the release of the hormones insulin and glucagon. See the section on metabolic syndrome for a discussion of insulin. The exocrine function of the pancreas is to assist in digestion. Pancreatitis may develop in patients with alcohol use disorders. Additionally, pancreatitis is a rare complication of treatment with some psychotropic medications, including clozapine, risperidone, olanzapine, and valproate. Pancreatitis is usually accompanied by elevations in serum amylase and lipase. Serum amylase levels may be fractionated into salivary and pancreatic components. Elevations in salivary levels are commonly observed in eating disorder patients who purge by self-induced emesis. When a pancreatic disease is suspected, serum lipase is typically measured. Elevations in amylase and lipase suggest pancreatic disease. Patients with eating disorders who purge often have elevated levels of serum amylase and normal levels of serum lipase.

Autoimmune and Inflammatory Disease

Psychiatric symptoms are highly comorbid in autoimmune and inflammatory conditions. In fact, autoimmune and inflammatory conditions sometimes present with psychiatric symptoms and thus should be included in the differential diagnosis for patients with compatible historical and clinical features.

Systemic Lupus Erythematosus. SLE is a chronic inflammatory disorder. Tests for SLE are based on the detection of antibodies formed as part of the disease. Antinuclear antibodies are found in virtually all patients with SLE at some point during the illness. An indirect immunofluorescence assay is used to detect antinuclear antibodies. This test can be positive in a variety of rheumatologic diseases. For this reason, a positive result usually is followed by additional tests, including a test to detect antidouble-stranded DNA antibodies. Anti-dsDNA antibodies, when associated with antinuclear antibodies, are strongly suggestive of a diagnosis of SLE. Anti-dsDNA antibodies often fluctuate with disease activity, may predict flares, and are often followed to monitor disease activity and response to treatment.

Neuropsychiatric manifestations of SLE include depression, cognitive impairment, delirium, mania, and psychosis. About 5% of patients with SLE experience psychosis. Cognitive dysfunction is common and may include apraxia, aphasia, and agnosia, along with impairments in abstract thinking, short- and long-term memory, judgment, and visual–spatial function. Depression is also highly comorbid in patients with SLE. Many of the neuropsychiatric symptoms of SLE are also caused by steroids, which are used to treat SLE exacerbations. It is not uncommon that patients with SLE experience depression when undergoing a course of steroids, but in more severe cases, patients may experience psychosis or steroid-induced mania. If patients require repeated steroid therapy, pretreatment with second-generation antipsychotics may reduce or eliminate steroid-induced psychosis.

Autoimmune or Paraneoplastic Encephalopathy. There is growing recognition and identification of antibodies that target the CNS, resulting in a variety of psychiatric and neurologic signs and symptoms. Though presentations vary, common presenting symptoms include cognitive impairment, mood symptoms, psychosis, seizure, and abnormalities of movement. Infrequently, patients may present with psychiatric symptoms in the absence of neurologic symptoms. These syndromes occur across the lifespan. Psychiatrists should suspect these disorders when patients have atypical presentations of psychiatric illness, especially when there are comorbid neurologic signs or symptoms.

There are currently a number of clinical laboratory evaluations for antibodies associated with paraneoplastic and autoimmune neuropsychiatric disorders. Antibodies may target either intracellular or extracellular antigens. Antibodies to intracellular antigens include anti-Hu, anti-Ma2, and anti-CRMP5, among others. Extracellular (synaptic) antibody targets include N-methyl-D-aspartate (NMDA) receptors, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, γ-aminobutyric acid (GABA) receptors, and voltage-gated potassium channel complex associated antibodies, that is, LGI1 and Caspr2, among others. Laboratory evaluations for CNS autoantibodies will certainly continue to grow as research continues; reputable laboratories should be consulted for up-to-date testing panels.

When an autoimmune or paraneoplastic encephalopathy is suspected, serum and CSF antibody testing, routine CSF studies, as well as EEG and brain MRI should be considered. These studies serve both to rule out other conditions (such as brain neoplasm) and may also provide supporting evidence for an autoimmune or paraneoplastic cause. Patients with autoimmune or paraneoplastic disorders may have mildly to moderately elevated WBC and protein in CSF. EEG may reveal seizure activity, epileptiform discharges, and/or focal or generalized slowing. MRI is often normal but may reveal signal hyperintensities on FLAIR or T2-weighted imaging sequences. The prompt identification of autoimmune or paraneoplastic neuropsychiatric disorders facilitates the rapid initiation of appropriate treatments.

Anti-NMDA receptor encephalitis, for example, is an autoimmune encephalitis in which a typically young adult female patient initially presents with mood symptoms, agitation, psychosis, or other variable psychiatric manifestations. (Of note, while majority young adult and female, the disorder can present in either sex and has been documented to occur across the lifespan). The rapid evolution of symptoms, often in combination with neurocognitive impairment and neurologic symptoms (e.g., movement abnormalities, seizures), can be worked up with serum and CSF antibody testing and pelvic ultrasound, which may reveal an ovarian teratoma. Treatment involves removal of the tumor, if found, steroid administration, IV immunoglobulin and/or plasma exchange, and sometimes second-line immunotherapies. The majority of patients slowly recover.

An 18-year-old female with no past medical or psychiatric history presented to the emergency department with abrupt onset of mood lability, paranoia, and auditory hallucinations. She was inattentive, difficult to engage, and exhibited echolalia. She had occasional flailing movements of her upper extremities. Collateral history from her father revealed that she had a generalized tonic–clonic seizure 1 day prior to presentation, for which she was evaluated in the emergency department and released home, with an appointment for outpatient neurologic follow-up. At her second emergency department visit in 2 days, EEG revealed epileptiform discharges. MRI was unremarkable. CSF examination revealed mildly elevated WBC (18 cells/μL) and modestly elevated protein (74 mg/dL). Infectious workup was negative. CSF antibody evaluation revealed IgG antibodies to the NMDA receptor, and autoimmune NMDA receptor encephalitis was diagnosed.

Other Autoimmune and Inflammatory Conditions. Autoimmune and inflammatory conditions ranging from multiple sclerosis (MS) to rheumatoid arthritis to inflammatory bowel disease are frequently associated with comorbid psychiatric illness, especially affective disorders. This is likely due to a variety of factors, including the psychosocial impact of chronic illness, treatment with medications that may have psychiatric side effects, as well as potential neurobiologic effects of inflammatory cytokines or direct involvement of the brain (e.g., MS). It is important to identify and treat comorbid psychiatric illnesses that cause suffering, worsen the quality of life, and threaten health outcomes. Similarly, it is important for psychiatrists to identify signs and symptoms of autoimmune and inflammatory conditions in their patients and refer them to specialists for appropriate care. When managing psychiatric patients who develop symptoms concerning autoimmune or inflammatory illness, referral to appropriate specialists who can order the appropriate medical assessment and laboratory evaluation is essential.

Neurologic Disorders

Many neurologic disorders have accompanying psychiatric symptoms. Neurodegenerative disorders, cerebrovascular disease, movement disorders, seizure disorders, and demyelinating disorders are often accompanied by psychiatric symptoms. Imaging studies, EEG, and neuromuscular studies, in addition to laboratory evaluations of blood and CSF, may be part of the diagnostic evaluation of these disorders.

Neoplastic Disorders

Infrequently, psychiatric symptoms may be the result of a primary or metastatic neoplasm involving the CNS. Most often, neurologic symptoms accompany psychiatric symptoms when there is a CNS tumor, but this is not always the case. Neuroimaging studies are the medical assessment of choice to rule out CNS tumors as etiologic for neuropsychiatric symptoms. Some other cancers, such as pancreatic cancer, are commonly accompanied by depression, even before the cancer has been diagnosed. In the setting of psychiatric symptoms accompanied by weight loss and new or concerning somatic symptoms (abdominal pain, jaundice, bowel changes, hemoptysis), a workup for malignancy may be indicated, depending upon patient demographics, risk factors, history, and examination findings. This may include positron emission tomography (PET) studies, as well as other targeted evaluations depending upon presenting signs and symptoms.

Head Trauma

In an acutely altered patient, trauma must be ruled out via history and physical examination, with head imaging supplementing the evaluation when indicated. Head computed tomography (CT) is superior at identifying bony deformities and acute bleeds and is thus generally preferred in the acute evaluation of altered mental status when there is suspicion for head trauma.

Genetic Disorders

Though many psychiatric disorders have been demonstrated to be heritable to a certain extent, classically inherited genetic disorders are not commonly included in the differential diagnosis of psychiatric illness. Occasionally, laboratory evaluation for genetic disorders is indicated. Sometimes there is a known family history of a genetic disorder that prompts evaluation. Other times, compatible clinical features and an astute clinician lead to a diagnosis of a genetic disorder, even in the absence of family history.

A 43-year-old male with a history of recurrent major depression presented with new-onset psychotic symptoms. Neurologic examination revealed chorea, which had reportedly developed over the past 2 years. The patient did not know his family history; he had been adopted as an infant. Genetic testing revealed an abnormally large number of trinucleotide repeats (CAG) in the *huntingtin* gene on chromosome 4. Huntington disease was diagnosed.

Huntington Disease. Huntington disease is an autosomal dominant disorder involving an excess of trinucleotide repeats in the *huntingtin* gene on chromosome 4. Laboratory evaluation for Huntington disease is most commonly indicated when there is a known family history, often in combination with compatible clinical features, or for planning purposes. Huntington disease is also known as Huntington chorea. The basal ganglia are affected, leading to a movement disorder dominated by chorea (involuntary, fidgety movements of the face and extremities). Dystonia, rigidity, and other movement abnormalities often occur as well. Cognitive deterioration and behavioral symptoms accompany the movement disorder, sometimes preceding it.

Wilson Disease. Wilson disease is a rare autosomal recessive disorder that leads to abnormal copper metabolism. The disorder leads to excessive copper deposition in the brain and liver and may result in decreased intellectual functioning, personality changes, psychosis, liver dysfunction, and movement disorder. Symptoms usually present in the second and third decades of life. Laboratory assessment for Wilson disease includes the measurement of serum ceruloplasmin, the transport protein for copper, which is low, and urine copper, measured in a 24-hour specimen, which is elevated.

Other Genetic Disorders. Other genetic disorders may sometimes be suspected, and laboratory evaluations may be ordered when a clinical history and examination is concerning for a genetic etiology. For example, Fragile X syndrome may be suspected in a child with intellectual disability or autism who has characteristic physical features such as large ears and a long face, particularly when there is a compatible family history of a similar disability. Other genetic disorders with associated neuropsychiatric symptoms include Prader–Willi syndrome, adrenoleukodystrophy, and other inborn errors of metabolism, among others. These disorders are rare; when a genetic disorder is suspected, the appropriate laboratory evaluation is determined in consultation with specialists.

Nutritional Deficiency

A number of nutritional deficiencies may have accompanying neuropsychiatric symptoms; clinical history and examination should provide clues regarding whether nutritional deficiency may be contributing to the patient’s neuropsychiatric presentation. Thiamine and folate deficiency are common in patients who abuse alcohol. Thiamine deficiency can lead to Wernicke encephalopathy and Korsakoff syndrome in severe cases. Blood thiamine concentration can be measured to assess for deficiency. However, for patients at known risk for thiamine deficiency, most clinicians simply order thiamine supplementation without first ordering laboratory evaluation of thiamine. Folate and B_{12} deficiency, among other nutritional deficiencies, may be associated with dementia, delirium, psychosis, fatigue, and personality changes. Low folate levels may be found in patients who abuse alcohol or have poor nutrition. Additionally, some medications such as methotrexate and phenytoin can lead to folate deficiency. B_{12} deficiency is usually the result of poor absorption due to pernicious anemia or gastric disease. Folate and B_{12} can be directly measured. The metabolic intermediaries methylmalonic acid and homocysteine may be useful in the assessment of folate and B_{12} deficiency, particularly when vitamin levels are in a borderline range where deficiency cannot be definitely ruled in or out. Many severe nutritional deficiencies can result in neuropsychiatric disturbances, but the aforementioned deficiencies are those most commonly assessed in psychiatric patients.

Intoxication/Toxic Exposure

Laboratory assessment for intoxication or toxic exposures may be indicated under several different circumstances. Routine urine toxicology is seldom beneficial for inpatient psychiatric admissions but can be very helpful if illicit substance use is suspected or if the source of a patient’s symptoms is unclear. For example, abrupt, new-onset paranoia may be due to a primary psychiatric disorder, but it also may be due to intoxication with a number of substances. Toxicology screening may also be helpful in the evaluation and management of substance use disorders. Finally, there may be a concern for environmental exposures or for accidental or intentional overdoses.

Laboratory studies in intoxicated adults may help to identify the cause or consequence of intoxication. When the patient is unable or unwilling to provide information about the source of intoxication, appropriate studies, in addition to toxicology studies, include calcium, serum BUN, Cr, CK, glucose, ketones, electrolytes, LFTs, magnesium, serum osmolality, and a urinalysis. Reproductive-age women should undergo urine pregnancy testing.

Testing for drugs of abuse usually is performed on urine specimens. It also may be performed on specimens of blood, breath (alcohol), hair, saliva, and sweat. Urine screens provide information about recent use of frequently abused drugs such as alcohol, amphetamines, cocaine, marijuana, opioids, and phencyclidine (PCP) along with 3,4-methylenedioxymethamphetamine (MDMA) (ecstasy). Savvy patients may attempt to avoid a positive urine drug screen by providing a sample from another patient, diluting the sample, or modifying it with additives that may interfere with the drug abuse screen. Many substances may produce false positives with urine drug screening tests. When a false positive is suspected, a confirmatory test may be requested.

In cases where it is unclear what agents that the patient may have ingested, it is useful to screen for salicylates and acetaminophen. In the early stages of overdoses with lethal amounts of these medications, there may be few clinical signs. However, if an overdose is detected early, then effective treatments are available.

Comprehensive qualitative toxicology screening is usually performed by liquid and gas chromatography. This may require many hours to perform and is rarely done in routine clinical situations. It is usually performed in patients with unexplained toxicity and an atypical clinical picture. Quantitative toxicology assessments may be useful in managing patients who overdose when combined with clinical assessment and knowledge of when the ingestion occurred. With the exception of alcohol, drug levels for substances of abuse are not usually determined. Instead, only the presence or absence of the drug is determined. There is usually not a meaningful or useful correlation between the level of the drug and clinical behavior.

Drug Abuse. Patients may be unreliable when reporting their substance use history. Substance-induced mental disorders often resemble primary psychiatric disorders. Furthermore, substance use can exacerbate pre-existing mental illnesses. Indications for ordering a drug abuse screen include unexplained behavioral symptoms, a history of illicit drug use or dependence in a new patient evaluation, or a high-risk background (e.g., criminal record, adolescents, and history of prostitution). A drug abuse screen also is frequently used to monitor patient abstinence during treatment of substance use disorders. Such tests can be ordered on a scheduled or random basis. Many clinicians believe random testing may be more accurate in the assessment of abstinence. The tests also may help to motivate the patient.

Other laboratory data may suggest a problem with substance abuse. An increase in the mean corpuscular volume (MCV) is associated with alcohol abuse. Liver enzymes may be increased with alcohol abuse or from hepatitis B or C acquired from IV drug abuse. Serologic testing for hepatitis B or C can confirm that diagnosis.

TESTED SUBSTANCES. Routine tests are available for PCP, cocaine, tetrahydrocannabinol (THC) (*marijuana*), benzodiazepines, methamphetamine, and its metabolite amphetamine, morphine, codeine, methadone, barbiturates, lysergic acid diethylamide (LSD), and MDMA (*ecstasy*). Different laboratories have varying thresholds for the detection of these substances. Some laboratories report a positive finding based only on the results of an initial screening test, whereas others require a second confirmatory test, often by a more sensitive or specific method.

Drug screening tests may have high false-positive rates. This is often due to the interaction of prescribed medication with the test, resulting in false-positive results and a lack of confirmatory testing. False-negative tests are common as well. False-negative results may be due to problems with specimen collection and storage. An unbroken chain of custody of the specimen is important. Patients may attempt to alter a specimen by dilution, by changing the pH (bleach and baking soda), or by using other additives (perfume and salt) that interfere with the test. Allowing a specimen to remain at room temperature too long may result in inaccurate testing.

The length of time that a substance can be detected in the urine is listed in Table 7.6–1. These are approximate times that are influenced by the frequency and duration of antecedent drug use and the presence of illnesses that could alter excretion, such as renal or hepatic disease.

Urine drug screens may detect some opiate metabolites up to 3 to 4 days after use.

Heroin is metabolized to 6-monoacetylmorphine, a metabolite unique to heroin. Because it can be detected with urine testing, it can be used to differentiate heroin from other opioids. False-positive drug screen results for opiate may occur in patients taking quinolones or rifampin. Poppy seeds have also been reported to produce false-positive results. Confirmation testing can identify false positives from quinolones or rifampin but may not be able to detect poppy seed use.

Patients using dronabinol for chemotherapy-induced nausea or HIV wasting syndrome will test positive for THC/marijuana. It is not possible to differentiate dronabinol from marijuana on urine drug screens.

Alcohol. There is no single test or finding on physical examination that is diagnostic for alcohol use disorders. The history of the pattern of alcohol ingestion is most important in making the diagnosis. Laboratory test results and findings on physical examination may help to confirm the diagnosis. Alcohol use disorders may be associated with telangiectasias, hepatomegaly, and evidence of trauma on physical examination. In patients with acute alcohol intoxication, a blood alcohol level (BAL) may be useful. A high BAL in a patient who clinically does not show significant intoxication is consistent with tolerance. The degree of alcohol intoxication can also be assessed using the concentration of alcohol in expired respirations (breathalyzer). BAL is used to legally define intoxication in the determination of whether an individual is driving under the influence. The legal limit in many states is 80 mg/dL. Importantly, the degree of clinical impairment is an individual matter that is a function of a patient’s tolerance. For example, a chronic alcohol user who maintains a daily BAL of 250 mg/dL may show less cognitive impairment than the occasional drinker with a BAL of 120 mg/dL. In general, however, a BAL in the range of 50 to 100 mg/dL is associated with impaired judgment and coordination and levels greater than 100 mg/dL produce ataxia.

Table 7.6–1.
Drugs of Abuse That Can Be Detected in Urine

Drug	Length of Time Detected in Urine
Alcohol	7–12 hours
Amphetamine	48–72 hours
Barbiturate	24 hours (short-acting); 3 weeks (long acting)
Benzodiazepine	3 days
Cocaine	6–8 hours (metabolites 2–4 days)
Codeine	48 hours
Heroin	36–72 hours
Marijuana	2–7 days
Methadone	3 days
Methaqualone	7 days
Morphine	48–72 hours

Alcohol withdrawal is often thought to begin when BAL approaches zero, but it is important to realize that withdrawal can occur at much higher BAL in chronic users of alcohol. For example, if one maintains a daily BAL of 250 mg/dL, withdrawal may begin 150 mg/dL because the degree and rate of change in BAL are associated with symptoms of withdrawal. Alcohol withdrawal presents with an elevation in blood pressure and pulse and a tremor. These symptoms commonly occur when serum alcohol levels are low or rapidly declining. Active intervention with benzodiazepines may be necessary to prevent the condition from progressing to alcohol withdrawal delirium, which is a medical emergency that may be fatal. Patients who consume large amounts of alcohol may require correspondingly large doses of benzodiazepines to treat withdrawal. When BAL is suspected of being low or undetectable, patients with alcohol use disorders should be assessed frequently to prevent the onset of withdrawal symptoms.

Common laboratory studies for the evaluation of a patient with the diagnosis of alcohol abuse or dependence include a CBC (to assess MCV and red cell distribution width [RDW] for a macrocytic profile), serum electrolytes (to obtain levels of magnesium and potassium, which are commonly low), and liver enzymes (to assess GGT, which is sensitive for acute alcohol abuse, along with AST and ALT). Alcoholic liver disease is characterized by elevations in AST and ALT, typically in a ratio of AST to ALT of 2:1 or greater. GGT may be elevated. Carbohydrate-deficient transferrin (CDT) may also be helpful in the identification of chronic heavy alcohol use. Total protein, serum albumin, and PT are assessed as indices of nutritional status and liver function. Folate and thiamine deficiencies are frequently present in patients with alcohol abuse. Urine toxicology screens for other drugs of abuse may be helpful in understanding the full clinical picture.

Environmental Toxins. Specific toxins are associated with a variety of behavioral abnormalities. Exposure to toxins may occur through occupation or hobbies. Aluminum intoxication can cause a dementia-like condition. Aluminum can be detected in the urine or blood. Arsenic intoxication may cause fatigue, loss of consciousness, anemia, and hair loss. Arsenic can be detected in urine, blood, and hair. Manganese intoxication may present with delirium, confusion, and parkinsonian syndrome. Manganese may be detected in urine, blood, and hair. Symptoms of mercury intoxication include apathy, poor memory, lability, headache, and fatigue. Mercury can be detected in urine, blood, and hair. Manifestations of lead intoxication include encephalopathy, irritability, apathy, and anorexia. A blood lead level is used to diagnose lead toxicity occurring over the past few weeks. The free erythrocyte protoporphyrin test is a test for lead toxicity over the past 3 months.

Significant exposure to organic compounds, such as insecticides may produce behavioral abnormalities. Many insecticides have strong anticholinergic effects. Presentation with the cluster of anticholinergic effects such as dry mouth, blurred vision, constipation, and urinary retention typically alerts clinicians to the possibility of toxicity. There are no readily available laboratory tests to detect these compounds. Poison control centers may assist in the identification of appropriate testing facilities.

Volatile Solvent Inhalation. Volatile substances produce vapors that are inhaled for their psychoactive effect. The most commonly abused volatile solvents include gasoline, glue, paint thinner, and correction fluid. The aerosol propellants from cleaning sprays, deodorant sprays, and whipped cream containers may be abused. Nitrites, such as amyl nitrite (“poppers”) and butyl nitrite vials (“rush”), and anesthetic gases, such as chloroform, ether, and nitrous oxide, are also abused.

Chronic abuse of volatile solvents is associated with damage to the brain, liver, kidneys, lung, heart, bone marrow, and blood. Abuse may produce hypoxia or anoxia. Signs of abuse include short-term memory loss, cognitive impairment, slurred and “scanning” speech, and tremor. Cardiac arrhythmias may occur. Exposure to toluene, which is present in many cleaning solutions, paints, and glues, has been associated with loss of clear gray–white matter differentiation and with brain atrophy on MRI scans. Methemoglobinemia has occurred with butyl nitrite abuse. Chronic use of volatile solvents is associated with the production of panic attacks and an organic personality disorder. Chronic use may also produce impairment in working memory and executive cognitive function.

Initial treatment is to prevent access to the drug and to allow clearing of the substance through the respiratory system. When hypoxia occurs, supplemental oxygen administration may be necessary. This will not only treat the hypoxia but will also facilitate the clearance of the inhaled chemical. Antiarrhythmic medication may be needed. Over the long term, patients will benefit from entering sobriety programs to prevent relapse.

Acetaminophen or Salicylate Overdose. Intentional or unintentional overdose with acetaminophen or salicylates requires medical and laboratory assessment. In an altered patient, especially those with past suicide attempts or suicidal ideation, laboratory evaluation for ingestions should be performed.

ACETAMINOPHEN. Acetaminophen is one of the most frequently used agents in intentional drug overdoses and is a common cause of overdose-related deaths. Sequelae of acute overdose most notably include hepatotoxicity and acute hepatic failure, and also acute renal failure in some cases as 4 g of acetaminophen can lead to acute hepatic failure. Chronic abusers of alcohol may be particularly vulnerable to hepatotoxicity following acetaminophen overdose.

After an overdose of acetaminophen, large amounts of toxic metabolites are formed as the primary metabolic pathways of sulfate and glucuronide conjugation become saturated. The toxic metabolite can be inactivated by glutathione. Acetylcysteine (Mucomyst) treatment, which protects the liver by maintaining appropriate concentrations of glutathione, must occur promptly after an overdose to prevent hepatotoxicity. Activated charcoal effectively binds acetaminophen. After an acetaminophen overdose, activated charcoal is often administered with acetylcysteine to prevent hepatotoxicity. The plasma acetaminophen concentration should be determined not less than 4 hours after ingestion of the overdose. If the initial determination shows a high concentration, then a full course of acetylcysteine should be administered. If a low plasma concentration is reported, then initiation or continuation of acetylcysteine treatment is not necessary. LFTs (serum AST, serum ALT, PT, and bilirubin) should be performed at 24-hour intervals for at least 96 hours postingestion if the plasma acetaminophen concentration indicates potential hepatotoxicity. If no abnormalities are detected within 96 hours, then further determinations are not needed.

SALICYLATE TOXICITY. Aspirin (salicylate) is also used for overdose, though it is less common than acetaminophen. Ingestion of sufficient amounts of aspirin may be fatal. Some patients with chronic inflammatory conditions and/or chronic pain may ingest large amounts of salicylates for therapeutic reasons. Ingestion of 10 to 30 g of aspirin may be fatal in adults. Most patients will develop symptoms of toxicity when salicylate levels are greater than 40 mg/dL (2.9 mmol/L). Signs and symptoms of toxicity include acid–base abnormalities, tachypnea, tinnitus, nausea, and vomiting. In cases of severe toxicity, symptoms may include hyperthermia, altered mental status, pulmonary edema, and death.

Treatment includes administration of multiple doses of activated charcoal as well as alkalinization of systemic pH by administering sodium bicarbonate. A salicylate level greater than 7.2 mmol/L is one of several absolute indications for hemodialysis following salicylate overdose. Renal failure, altered mental status, and pulmonary edema are other indications for hemodialysis.

The Role of Brain Imaging in Diagnosis

Brain imaging can be broadly divided into two domains: Structural and functional. Structural imaging provides detailed, noninvasive visualization of the morphology of the brain. Functional imaging provides a visualization of the spatial distribution of specific biochemical processes. Structural imaging includes x-ray, CT, and MRI. Functional imaging includes PET, single-photon emission computed tomography (SPECT), functional MRI (fMRI), and magnetic resonance spectroscopy (MRS). With the limited exception of PET scanning, functional imaging techniques are still research tools that are not yet ready for routine clinical use.

A common clinical dilemma involves whether to obtain an MRI or a CT scan. CT scans usually are less expensive and more commonly available. Although CT scans are a relatively inexpensive screening examination, most clinicians have a hypothesis-based approach to the selection of an imaging modality: The question that they need to be answered drives the selection of the scan. The following subsections provide some guidance regarding the relative advantages of MRI scans and CT scans.

Currently, the use of structural imaging techniques is limited to the identification of nonpsychiatric disease. Scans are performed when a clinician suspects or seeks to rule out a nonpsychiatric illness. Attempts to use structural imaging techniques to subcategorize various psychiatric illnesses have not yielded data that are useful in clinical practice. Consequently, structural imaging techniques are not useful for making psychiatric diagnoses.

Neuroimaging in patients with dementia is associated with some degree of controversy. This is due to the large number of scans that do not have clinically significant findings. Some argue that noncontrast MRI scans or CT scans are useful screening for all dementia patients at the time of initial diagnosis. A contrasting point of view suggests that the probability of significant findings is greater in patients younger than 60 years of age, those with focal findings on the neurologic examination, or recent onset of symptoms.

Findings in patients with dementia may include atrophy, either focal or generalized and white matter lesions. These are nonspecific changes.

Imaging in delirious patients is unlikely to alter management. This is particularly true when there is no history of head trauma or loss of consciousness, and there are no focal findings on the neurologic examination. Imaging may be performed if the delirious patient fails to respond to treatment or has limited responsiveness or alertness. Imaging in delirious patients may reveal underlying factors that may predispose the patient to delirium. However, it is less common that these are etiologic factors.

Magnetic Resonance Imaging. MRI scans are used to distinguish structural brain abnormalities that may be associated with a patient's behavioral changes. These studies provide the clinician with images of anatomical structures viewed from cross-sectional, coronal, or oblique perspectives. MRI scans can detect a large variety of structural abnormalities. The MRI is particularly useful in examining the temporal lobes, the cerebellum, and deep subcortical structures. It is unique in its ability to identify periventricular white matter hyperintensities. MRI scans are useful in examining the patient for particular diseases, such as nonmeningeal neoplasms, vascular malformations, seizure foci, demyelinating disorders, neurodegenerative disorders, and infarctions. Advantages of MRI include the absence of ionizing radiation and the absence of iodine-based contrast agents. Contrast agents are based on gadolinium, a rare earth metal, and usually do not provoke an allergic response.

MRI scans are not always obtained with the same parameters. The nature of the scan is modified in a manner that is most likely to provide data relevant to the clinical hypothesis that generated the request for the scan. For this reason, clinicians should provide the radiologist with clear, concise indications for the scan. Scan parameters include modes referred to as T1 and T2. T1-weighted scans provide detailed visualizations of brain anatomy. Extracellular fluid, such as edema, looks dark. In contrast, T2-weighted scans reveal a white pattern for edema. These scans are useful in examining the patient for white matter disease.

MRI scans are contraindicated when the patient has a pacemaker, aneurysm clips, or ferromagnetic foreign bodies.

Research currently uses a variant of MRI scanning called functional MRI (or fMRI) that is able to measures blood oxygenation levels in the brain while people are performing tasks in the scanner. Such studies have identified potential neural biomarkers of treatment response and the potential to be combined with other measures to personalize treatment for mental illness. Still, other work suggests that neuroimaging may be informative in providing evidence of “bottom-up” or neurophysiologically based methods of defining mental illness, in contrast to current symptom-based approaches.

Computed Tomography. CT scans are used to identify structural brain abnormalities that may contribute to a patient’s behavioral abnormalities. These studies provide the clinician with cross-sectional x-ray images of the brain. CT scans can detect a large variety of structural abnormalities in the cortical and subcortical regions of the brain. CT scans are useful when a clinician is looking for evidence of a stroke, subdural hematoma, tumor, or abscess. These studies also permit the visualization of skull fractures. CT scans are the preferred modality when there is suspicion of a meningeal tumor, calcified lesions, acute subarachnoid or parenchymal hemorrhage, or acute parenchymal infarction. These scans have some resolution limits in the posterior fossa and the inferior surfaces of the temporal lobes owing to artifacts created by the skull. CT scans are not as successful in detecting focal gliosis as MRI scans.

CT scans may be performed with or without contrast media. The purpose of contrast is to enhance the visualization of diseases that alter the blood–brain barrier, such as tumors, strokes, abscesses, and other infections. Contrast agents are administered by IV means. Allergic reactions to contrast agents may occur and can include an anaphylactic reaction with cardiovascular collapse. This type of reaction most commonly occurs in patients with asthma or allergies to seafood.

Indications for a CT scan are not agreed upon in the literature. Less controversial indications include focal findings on the neurologic examination or abnormalities on an EEG. Slightly more controversial indications include impaired cognition on the mental status examination, first episode of psychosis (especially if the presentation is atypical), delirium, late-onset (after 50 years of age) personality disorders, psychosis, or affective illness. Prolonged catatonia is also a possible indication.

The Role of the Electroencephalogram in Diagnosis

The EEG is the assessment of regional cerebral cortical electrical activity. Clinical neuroscience has a long history of using the EEG. The EEG can be used in different ways to study specific brain states or activities by modifications to the technique of data collection or to the data itself. EEG data can be displayed on paper tracings in the manner of conventional EEG recordings. Alternatively, the data can be digitized and transformed to yield color-coded topographic brain maps of regional activity. The collection periods can be prolonged, and the data can be electronically displayed along with video monitoring of the patient to provide telemetry assessments of patients with epilepsy. Telemetry assessments are typically performed in an effort to correlate behavioral abnormalities with brain electrical activity as part of the workup of seizure disorders.

Prolonged periods of EEG recording during sleep, when coupled with a recording of a limited lead ECG and facial muscle activity, result in the sleep EEG or polysomnography. Many clinicians also use the EEG to monitor ECT administration.

Clinicians use the EEG to localize seizure foci and to evaluate delirium. The EEG and its topographical descendants have not found a clear role in the diagnostic assessment of psychiatric patients, although EEG is being investigated as a biomarker of psychiatric disorders. The EEG is usually used in psychiatry to rule out nonpsychiatric disease, such as seizure disorders or delirium, as a cause of psychiatric symptoms. When the differential diagnosis includes strokes, tumors, subdural hematomas, or dementia, the yield is usually higher with imaging tests. Not surprisingly, the yield is the highest in patients with a history of a seizure disorder or a clinical history that is strongly suggestive of a recent seizure or other organic illness. Such clinical features would include a history of altered consciousness, atypical hallucinations (e.g., olfactory), head injury, and automatism. In addition, the EEG is commonly obtained when there is an abnormal CT or MRI. It is important to remember that seizures are a clinical diagnosis; a normal EEG does not rule out the possibility of a seizure disorder.

When a conventional EEG does not demonstrate the dysrhythmia (abnormal bursts of spike, sharp wave, or slow activity) associated with seizures, other measures can be taken to enhance the sensitivity of the evaluation. These measures include sleep deprivation, hyperventilation, and photic stimulation. Detection also can be improved through the use of nasopharyngeal leads, computer-transformed recordings, and evoked potentials (EPs). Sleep deprivation assists in seizure detection by a simple mechanism. Patients are more likely to fall asleep during the EEG after a period of sleep deprivation. It is during the changes in consciousness associated with various stages of sleep that the spike and sharp wave activity associated with seizure disorders is more likely to be detected. Hyperventilation, usually for approximately 3 minutes, may produce slow-wave activity or spike waves. Photic stimulation consists of exposing the patient to a flashing strobe light during the EEG. Abnormal wave activity not synchronized to the flashing light is pathologic. Studies involving the use of nasopharyngeal leads, although uncomfortable for the patients, may increase the yield of positive findings when there is a suspicion of temporal lobe epilepsy.

The EEG can be helpful in patients with altered consciousness by identifying contributing conditions. Nonconvulsive seizures lack motor manifestations but impair consciousness. Nonconvulsive status epilepticus may also cause impairment in consciousness.

Encephalopathies due to underlying metabolic alterations may show diffuse bilateral slowing of the background rhythm along with moderate or high wave amplitude. Specific EEG findings are more commonly seen in some conditions, such as the triphasic waves found in hepatic encephalopathy or periodic sharp wave complexes in Creutzfeldt–Jakob disease.

Evoked Potential. EP testing is the measurement of the EEG response to specific sensory stimulation. The stimulation may be visual, auditory, or somatosensory. During visual EPs, the patient is exposed to flashing lights or a checkerboard pattern. With auditory EP, the patient hears a specific tone. In somatosensory EP, the patient experiences an electrical stimulation to an extremity. These stimuli repeatedly occur while the patient undergoes a routine EEG. Using a computer, the responses to these stimuli are recorded and averaged. The time frame is measured in milliseconds. These tests are useful in neurology and neurosurgery. For example, they assist in the assessment of demyelinating disorders such as MS. In psychiatry, EP testing may help in the differentiation of organic from functional impairments. A classic example is the use of EP testing to evaluate possible functional blindness. The usefulness of these tests in psychiatry is still under investigation.

Polysomnography. Polysomnography is used to assess disorders of sleep by concurrently assessing the EEG, ECG, blood oxygen saturation, respiration, body temperature, electromyogram, and electrooculogram. Polysomnography has demonstrated an increase in the overall amount of rapid eye movement (REM) sleep and a shortened period before the onset of REM sleep (decreased REM latency) in patients with major depression. Polysomnography is useful in diagnosing comorbid sleep disorders so that appropriate treatment can be initiated.

A 57-year-old obese male with recurrent major depressive disorder presents for follow-up evaluation of his depression. He has had a worsening of his mood as well as worsening of fatigue and daytime drowsiness. His wife reports that he snores each night loudly. A sleep study is ordered and completed, and obstructive sleep apnea is diagnosed. The patient's fatigue and daytime drowsiness improve with the use of a continuous positive air pressure (CPAP) machine.

TREATMENT SELECTION AND MONITORING

Medical and laboratory assessments are important not only in the diagnostic assessment of patients with neuropsychiatric symptoms or disorders but are also important in ensuring the safe initiation and monitoring of appropriate treatments. Pretreatment assessments may be necessary to determine the safety of recommended treatments. Many treatments for psychiatric disorders require routine monitoring of drug levels and/or physical health parameters, which may be adversely impacted by treatments. A summary of suggested laboratory assessments for selected psychotropic agents is provided in Table 7.6–2. Finally, suspected complications of psychiatric treatment may also prompt medical and laboratory assessments in psychiatric patients.

Medical Clearance for Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is typically used for patients with severe or treatment-resistant depression, catatonia, psychotic depression, and in some cases of treatment-refractory psychosis. Typical laboratory tests obtained before the administration of ECT include a CBC, serum electrolytes, urinalysis, and LFTs. However, no specific laboratory tests are required in the pre-ECT evaluation. Usually, an ECG is also obtained. A spinal x-ray series is no longer routinely indicated because of the low risk of spinal injury associated with modern administration techniques that use paralyzing agents. A comprehensive medical history and physical examination are useful screening tools to identify possible conditions that could complicate treatment. Patients with a complex or concerning medical history may require a more extensive evaluation prior to initiating ECT; these additional evaluations are usually guided by evaluating consultants with expertise in medically assessing patients' risk level for undergoing procedures under anesthesia.

Electrocardiogram in Treatment Selection and Monitoring

The ECG is a graphical representation of the electrical activity of the heart. Abnormalities in this activity correlate with cardiac pathology. The ECG is most commonly used in psychiatry to assess the side effects of psychotropic medications.

Many psychotropic medications, including antipsychotics and antidepressants, have been associated with prolongation of the QT interval. The corrected QT interval (QTc) is of importance because lengthening of the QTc is associated with subsequent development of a potentially fatal arrhythmia Torsades de pointes. While the QTc interval alone is not a strong predictor of Torsade de pointes, a QTc greater than 450 msec is associated with increased risk in conjunction with other risk factors including older age (>65 and especially >75), female sex, history of arrhythmia, congestive heart failure, cardiac conduction defects, and concurrent use of arrhythmogenic medication. For this reason, clinicians may elect to obtain an ECG before initiation of treatment with agents known to prolong the QT interval, particularly if the patient has other risk factors for prolonged QT interval. Further, bradycardia, hypokalemia or hypomagnesemia, or the concurrent use of other drugs that prolong the QT interval all increase the risk for arrhythmias. When a patient in need of psychotropic medication has a prolonged QT interval, the use of agents with low or no risk for further prolonging the QT interval is recommended when possible. This assessment, and the selection of agents most likely to help but not harm the patient, requires a careful risk/benefit analysis.

Tricyclic or tetracyclic antidepressants (TCAs) are associated with ECG changes. Anticholinergic effects may increase heart rate. Prolongation of the PR, QT, and QRS intervals, along with ST-segment and T-wave abnormalities, may occur. The TCAs can cause or increase pre-existing atrioventricular or bundle branch block. Many clinicians obtain an ECG before beginning a TCA in a patient older than 40 years of age and in any patient with known cardiovascular disease.

Table 7.6–2.
Suggested Laboratory Monitoring for Selected Psychotropic Agents

Psychotropic Agent	Baseline	Routine Monitoring
Atypical antipsychotics	Fasting lipid panel, hemoglobin A1c/fasting blood glucose ECG if patient has risk factors for QT prolongation	At 12 weeks, 1 year, and then annually: fasting lipid panel, fasting blood glucose/hemoglobin A1c
Clozapine	CBC with differential (in addition to baseline labs for atypical antipsychotics)	CBC with differential: weekly for 6 months, every other week for an additional 6 months, and then every 4 weeks, if no abnormalities in WBC or ANC
Lithium	BMP, TSH, CBC, Calcium, pregnancy test ECG if >40 or with known cardiac risk factors	Weekly lithium trough level during dose titration until stable therapeutic drug level is achieved, then every 3–6 months Every 6 months: BMP, TSH, and calcium Therapeutic serum levels: 0.6–1.2 mEq/L (for acute mania: 0.8–1.2 mEq/L)
Valproate	CBC, LFTs, pregnancy test Avoid in women with childbearing potential	Obtain trough valproic acid level 1–2 weeks after initiation and each dosing change, then as clinically indicated. At 6 months and then annually: CBC, LFTs Therapeutic serum levels: 50–125 µg/mL (for acute mania: 85–125 µg/mL)
Carbamazepine	CBC, LFTs, BMP, pregnancy test	Serum carbamazepine levels: obtain weekly levels until stable, then every 3–6 months.

	In patients of Asian ancestry, avoid use or first obtain genetic testing for HLA-B*1502 allele	CBC: 2 weeks after dosage changes, 2 months after initiation, and then every 6 months LFTs and BMP: every 6 months Therapeutic serum levels (in seizure disorders): 4–12 μg/mL
Oxcarbazepine	BMP, pregnancy	Only as clinically indicated
TCAs	ECG if >40 or with known cardiac disease or risk factors	Blood levels as clinically indicated Therapeutic serum levels: Nortriptyline[a]: 50–150 ng/mL Desipramine[a]: >125 ng/mL Imipramine (desipramine + imipramine): >200 ng/mL

[a] frequency of serious side effects may increase over 300 ng/mL.

BMP, Basic metabolic panel; ECG, electrocardiogram; CBC, complete blood count; WBC, white blood cell; ANC, absolute neutrophil count; TSH, thyroid-stimulating; LFT, liver function test.

Lithium therapy can cause benign reversible T-wave changes; rarely, it can impair sinoatrial (SA) node function and can cause heart block. ECGs are often obtained before initiation of treatment with lithium if there are risk factors for coronary artery disease. An ECG is obtained in cases of lithium toxicity or overdose.

In treating patients with eating disorders, it may be reasonable to obtain ECG as patients commonly have low potassium levels that may result in abnormal ECG recordings. As the serum potassium drops below normal, T waves become flattened (or inverted), and U waves may appear.

Metabolic Monitoring

Metabolic syndrome is an important complication that can result from a number of antipsychotics. Consequently, prior to initiating antipsychotic therapy, it is important to assess. Prior to initiating certain psychotropic agents, particularly second-generation antipsychotics, it is important to pursue baseline medical and laboratory assessments, including measurement of weight, blood pressure, fasting glucose or hemoglobin A1c and fasting lipid profile. The risk of metabolic syndrome varies with different second-generation antipsychotic medications, and the choice of medication should be chosen with this in mind.

Many psychotropic drugs, including antidepressants, mood stabilizers, and antipsychotic medications, have weight gain as a potential side effect. Weight gain can lead to obesity, a major risk factor for the development of multiple medical problems such as hypertension, diabetes, cardiovascular disease, cerebrovascular disease, and lipid abnormalities. Weight gain can also contribute to medication nonadherence and poor self-image. Waist circumference measuring greater than 35 in for a woman or 40 in for a man also is of similar concern. Initial intervention to address weight gain typically includes education and initiation of an appropriate diet and exercise program. Discontinuation of the offending medication and substitution, if possible, with a medication less likely to give rise to weight gain also may be an appropriate intervention.

Weight. Obesity is associated with a heightened risk of coronary artery disease, stroke, type II diabetes mellitus, dyslipidemia, hypertension, and osteoarthritis. Treatment with first-generation antipsychotic agents as well as atypical agents is associated with obesity, although there is a significant variation between agents in the propensity to produce obesity. Clozapine and olanzapine are the most likely to produce weight gain. Aripiprazole, ziprasidone, and lurasidone have a substantially lower risk for producing weight gain. All patients with schizophrenia and patients taking atypical antipsychotic medications should have their weight monitored. Likewise, patients with anxiety or mood disorders who take antidepressants or mood stabilizers associated with weight gain should have their weight monitored. Measurement of waist circumference may be used as a risk indicator. Men with a waist larger than 40 in and women with a waist larger than 35 in are at increased health risk. Education about the role of a healthy diet and exercise in preventing weight gain is effective. It is easier to prevent weight gain than it is to lose weight. Many methods proposed to reduce weight are ineffective.

Body Mass Index. BMI values above 25 are associated with an increased risk for the illnesses noted above. Some clinicians advocate regular monitoring of BMI by both patient and clinician for patients with schizophrenia or other patients taking atypical antipsychotic medication and recommend intervention in the form of nutritional counseling, exercise program, or change in antipsychotic medication when BMI increases by one unit.

Monitoring of weight and body mass index (BMI) is important in the management of many patients with psychiatric illness. A variety of psychiatric illnesses can affect appetite and may cause weight loss or weight gain. Measurement of weight may be useful in assessing response to treatment and recovery.

Fasting Blood Sugar. Atypical antipsychotic agents have been associated with abnormalities in serum glucose levels, including the development of diabetes mellitus. Many clinicians monitor their patients who take atypical antipsychotic agents for the development of hyperglycemia by obtaining fasting blood glucose levels and glycosylated hemoglobin levels on a quarterly or semiannual basis. In addition, extremes in serum glucose concentrations have been associated with delirium. Evaluation for diabetes or other abnormalities in glucose metabolism is usually best done by specialists.

Glycosylated Hemoglobin. Glycosylated hemoglobin (hemoglobin A1c) is a correlate of the mean serum glucose concentration over the preceding 8 to 12 weeks. New hemoglobin is formed free of attached glucose. Because red cells are permeable to glucose, the sugar becomes permanently attached to hemoglobin at a concentration proportional to the serum glucose concentration. Thus, hemoglobin A1c is a measure of the mean blood glucose concentration over the prior 8 to 12 weeks. A normal hemoglobin A1c level is below 5.7%. A hemoglobin A1c level of 6.5% or above indicates diabetes mellitus. Levels between 5.7 and 6.4 indicate an increased risk of developing diabetes. For patients with diabetes, a hemoglobin A1c level of 7% or less is a common treatment target.

Lipids. Hyperlipidemia, including elevated cholesterol and triglyceride levels, is associated with cardiovascular and cerebrovascular disease. Certain antipsychotic medications, including clozapine and some of the second-generation antipsychotics, have been associated with hyperlipidemia. Fasting lipid panels should be evaluated prior to initiation of medications associated with dyslipidemia, at 12 weeks into treatment, and annually thereafter.

Psychotropic Medications: Serum Levels and Physical Health Monitoring

Testing to determine blood concentrations of certain psychotropic medications enables the clinician to ascertain whether blood levels of medications are at therapeutic, subtherapeutic, or toxic levels. Psychiatric symptoms are not uncommon when prescribed medications are at toxic levels. Among older adults and patients with severe medical conditions, severe reactions may occur even within typical therapeutic ranges.

Blood levels of psychotropic medications often are obtained when a patient displays mental status changes after a dosage change, after an overdose or suspected overdose, or to assess medication compliance.

Serum concentrations of psychotropic medications are assessed to minimize the risk of toxicity to patients receiving these medications and to ensure the administration of amounts sufficient to produce a therapeutic response. This is particularly true for medications with therapeutic blood levels. Medication levels are often influenced by hepatic metabolism or renal clearance.

Cytochrome P450 enzymes (CYPs) are important in the hepatic metabolism of drugs. Some drug substrates induce or inhibit CYP activity. Induction results in acceleration of drug metabolism and a resultant decrease in the levels of agents metabolized by that particular CYP. Administration of drugs that inhibit CYPs may result in higher drug levels of agents metabolized by the inhibited CYP. Genetic variation also influences CYP activity. Genotypes at a particular CYP, such as CYP2D6, may lead to any of the following phenotypes: ultrarapid metabolizer, extensive metabolizer, intermediate metabolizer, or poor metabolizer. At usual doses of a given medication, individuals with the poor metabolizer phenotype may have high serum levels of CYP2D6 metabolized drugs due to the poor ability of CYP2D6 to metabolize the drug. Inversely, ultrarapid metabolizers may have very low levels of a drug due to rapid metabolism.

Antipsychotic Agents. Serum concentrations are not routinely obtained for most antipsychotic medications. Management usually consists of titration of the prescribed dose to levels that achieve reasonable symptomatic control and acceptable side effects. However, in some cases, blood levels may be helpful. These situations include suspected medication noncompliance and cases of poor response in the context of clinically adequate doses. In the latter scenario, the concern may include rapid hepatic metabolism.

Atypical antipsychotic agents may be associated with the development of metabolic syndrome. Therefore, appropriate laboratory monitoring should occur at regular intervals. At the initiation of treatment with an atypical antipsychotic medication, a clinician should obtain a fasting lipid profile and fasting blood glucose or hemoglobin A1c. This assessment should be repeated in 3 months and annually thereafter. Lipid profile and blood glucose should be repeated sooner if the patient experiences significant weight gain or symptoms suggestive of diabetes. A measurement of weight, BMI, and waist circumference also should be obtained at the initiation of treatment with an antipsychotic agent. These variables should be assessed monthly for the first 3 months of treatment and then at quarterly intervals. Baseline assessment should also include a personal or family history of obesity. Many clinicians will switch to a different antipsychotic agent when a 5% or more weight gain has occurred. Alternatively, if a medication change is not clinically indicated, adjunctive treatment with metformin may be considered.

CLOZAPINE. Clozapine (Clozaril) levels are trough levels determined in the morning before administration of the morning dose of medication. Though a therapeutic range for clozapine has not been established, a level of 100 ng/mL is widely considered to be the minimum therapeutic threshold. Although concentrations between 200 and 700 ng/mL may correlate more with response, nonresponse does occur within this range. Studies suggest that plasma levels of clozapine in the range of 200 to 400 ng/mL may lead to the achievement of maximal clinical efficacy; however, there is great variability among patients in terms of response and side effects at given dosages. One study demonstrated that patients with refractory schizophrenia who responded to clozapine were more likely to have clozapine blood levels of greater than 350 ng/mL. The risk of seizures increases with clozapine dosages of 600 mg/day or greater.

Clozapine is a common cause of leukopenia in psychiatry. A baseline CBC must be determined prior to the initiation of treatment. The baseline WBC count must be at least 3,500/mm^3, and the absolute neutrophil count (ANC) must be at least 2,000/mm^3 for initiation of therapy. Weekly CBCs are required during the first 6 months of treatment with clozapine because of the risk of agranulocytosis. Results must be sent to the dispensing pharmacy for the patient to receive his or her medication. Clozapine should be held for a WBC of less than 3,000/mm^3 or an ANC of less than 1,500/mm^3. For WBC 3,000 to 3,500/mm^3 and/or ANC 1,500 to 2,000/mm^3, clozapine may be continued, but the frequency of WBC and ANC monitoring is increased to twice weekly. If the WBC remains greater than 3,500/mm^3 and the ANC remains above 2,000/mm^3 during the first 6 months of clozapine treatment, then monitoring may be reduced to every other week for the next 6 months. If both the WBC and the ANC remain at appropriate levels after the second 6 months of treatment, then monitoring can be further decreased to every 4 weeks.

After clozapine discontinuation, clinicians usually monitor the CBC for an additional 4 weeks if laboratory values are within normal limits. If clozapine treatment was interrupted or discontinued due to abnormal laboratory values, the degree of severity of leukopenia or granulocytopenia determines whether daily, twice-weekly, or weekly laboratory monitoring is required. Ongoing monitoring is required until the WBC is at least 3,500/mm^3 and the ANC is at least 2,000/mm^3, and for at least 4 weeks from the date of clozapine discontinuation.

When moderate leukopenia or granulocytopenia develops (WBC between 3,000 and 2,000/mm^3 and/or an ANC between 1,500 and 1,000/mm^3), clozapine treatment must be interrupted, but the patient may be retreated with clozapine in the future. Repeat exposure to clozapine may occur once the WBC is at least 3,500/mm^3 and the ANC is at least 2,000/mm^3. These patients require weekly monitoring for a year after the reinstatement of clozapine. Subsequently, the frequency of monitoring may be reduced to every other week for 6 months and then further reduced to every 4 weeks. If granulocytopenia or leukopenia are severe (WBC <2,000/mm^3 and/or ANC <1,000/mm^3), the patient should not be rechallenged with clozapine in the future, regardless of WBC and ANC recovery.

If there is a break in clozapine treatment lasting less than 1 month during the period of weekly monitoring and the WBC consistently has been greater than 3,500/mm^{3,} and the ANC consistently has been greater than 2,000/mm^3, then treatment may resume with weekly monitoring. In addition, the patient will be eligible to reduce the frequency of monitoring to every other week after 6 months of total treatment rather than after 6 months from the time of the break in treatment. However, if the break in clozapine treatment lasts more than 1 month, then the patient must have a continuous 6 months of weekly monitoring without abnormalities before reducing the frequency of monitoring to every other week.

A similar rule applies for patients on clozapine for at least 6 months. If there is a break in clozapine treatment lasting less than 1 month in a patient undergoing CBC monitoring every other week and the WBC has been consistently greater than 3,500/mm^3 and ANC consistently has been greater than 2,000/mm^3, then the patient must undergo weekly monitoring for 6 weeks. Thereafter, the patient may resume every other week monitoring. However, if the break in treatment is longer than 1 month, then the patient must resume weekly monitoring for 6 months.

For a patient on clozapine for more than 1 year, a similar rule applies. If there is a break in clozapine treatment lasting less than 1 month in a patient undergoing monitoring every 4 weeks and WBC consistently has been greater than 3,500/mm^3 and ANC consistently has been greater than 2,000/mm^3, the patient has been taking clozapine for longer than 1 year, and the gap in treatment is for less than 30 days, then they may resume treatment with weekly monitoring for 6 weeks and then return to monthly monitoring. However, if the treatment gap has been longer than 30 days, then monitoring must be weekly for 6 months, then every other week for another 6 months, and then monthly monitoring may resume.

CLOZAPINE-ASSOCIATED MYOCARDITIS OR CARDIOMYOPATHY. Infrequently, clozapine treatment may precipitate myocarditis or cardiomyopathy. If patients taking clozapine develop new cardiac or respiratory symptoms concerning for myocarditis or cardiomyopathy, a medical evaluation should ensue with the assistance of specialists. Medical and laboratory assessment may include ECG, evaluation of cardiac biomarkers such as troponin, and echocardiography. Echocardiography is the visualization of cardiac anatomy by the use of computer-transformed echoes of ultrasound.

Psychiatry was consulted to evaluate a 36-year-old woman with schizophrenia who had been started on clozapine approximately 1 month ago and had been admitted to medicine 1 day ago with fever, tachycardia, and dyspnea. The primary team was concerned about NMS due to her autonomic symptoms. In addition to holding the clozapine, the psychiatrist recommended a cardiology evaluation due to the possibility that the patient's symptoms represented clozapine-induced myocarditis. The patient had nonspecific ECG changes, elevated cardiac troponins, and left ventricular dysfunction on echocardiogram; myocarditis was diagnosed.

NEUROLEPTIC MALIGNANT SYNDROME. Neuroleptic malignant syndrome (NMS) is a rare, potentially fatal consequence of neuroleptic administration. The syndrome consists of altered mental status, generalized rigidity (often severe), hyperthermia, and autonomic instability. Sustained muscle contraction, as well as impaired central mechanisms of thermoregulation, result in peripheral heat generation and muscle breakdown. Muscle breakdown contributes to elevated levels of creatine kinase (CK). Leukocytosis and low serum iron concentration are common. Myoglobinuric acute renal failure may occur due to rhabdomyolysis. Liver enzymes may become elevated. Patients may die from hyperpyrexia, aspiration pneumonia, renal failure, hepatic failure, respiratory arrest, or cardiovascular collapse. Treatment includes discontinuation of the neuroleptic, hydration, and general supportive care. Administration of dantrolene (a muscle relaxant) or bromocriptine (a dopamine agonist) may be considered, along with other treatments that have anecdotal success, including amantadine, benzodiazepines, or ECT. Data is limited with regard to the efficacy of any of these specific therapies.

A typical laboratory workup of NMS includes a CBC, serum electrolytes, BUN, Cr, and CK, as well as evaluation for other serious neurologic or medical conditions that may be mistaken for NMS. A urinalysis, including an assessment of urine myoglobin, is also usually performed. As part of the differential diagnosis, blood and urine cultures are performed as part of a fever workup. Pronounced elevations in the WBC may occur in NMS. WBCs are typically in the range of 10,000 to 40,000/mm^3.

CK elevations are typically more than 1,000 IU/L. Moderate elevations in CK may occur in the earliest stages of the disease. CK level may be normal or near-normal if significant rigidity has not yet developed. Other causes of muscle injury leading to increases in serum CK levels may include repeated intramuscular (IM) injections, prolonged or agitated periods in restraint, or dystonic reactions from neuroleptic administration. Importantly, elevated CK levels in the absence of hyperthermia and rigidity are not indicative of NMS.

Mood Stabilizers

CARBAMAZEPINE. Carbamazepine (Tegretol) may produce changes in the levels of WBCs, platelets, and, under rare circumstances, red blood cells. Aplastic anemia, thrombocytopenia, agranulocytosis, exfoliative dermatitis, and hepatic failure may all occur but are rare. Hyponatremia is common, particularly in the older adults. Pretreatment evaluation typically includes a CBC with differential and platelet count, as well as LFTs and renal function tests. Given the risk for hyponatremia, baseline serum electrolytes may also be obtained, particularly in more vulnerable populations such as the older adults.

The risk of exfoliative dermatitis (e.g., Stevens–Johnson syndrome) is greater in patients with the HLA-B*1502 allele. This allele is more common in patients of Asian descent and is largely absent in individuals of other ethnic backgrounds. Prior to initiating carbamazepine, genetic testing for this allele should be pursued in patients with ancestry, which puts them at a higher likelihood of having the HLA-B*1502 allele. If this allele is identified, that patient should not be treated with carbamazepine. Many clinicians monitor the CBC and LFTs every 2 weeks for the first 2 months of administration. Then, if the laboratory values have been within normal limits, CBC, serum carbamazepine level, and LFTs are monitored every 3 to 6 months. Patients should be cautioned to watch for petechiae, fever or signs of infection, pallor, or undue weakness, as well as signs and symptoms of hepatic injury or dermatologic reactions.

Carbamazepine is teratogenic and may produce a variety of congenital abnormalities, including neural tube defects. A pretreatment urine pregnancy test usually is obtained in women of child-bearing years, and women should be cautioned to use adequate contraception when taking carbamazepine. Carbamazepine may decrease plasma concentrations of hormonal contraceptives.

When used as an anticonvulsant, target blood levels for carbamazepine are 4 to 12 μg/mL. Target blood levels have not been established for mood disorder patients, but most clinicians aim for a level in this range before discontinuation of carbamazepine owing to lack of efficacy. Levels should be obtained before the morning dose and after the patient has taken the same total daily dose for a minimum of 5 days. Serum levels of carbamazepine can help establish an effective dose for an individual patient. Toxic side effects are common with levels greater than 15 μg/mL.

Manifestations of toxicity may include nausea, vomiting, urinary retention, ataxia, confusion, drowsiness, agitation, or nystagmus. Patients who exhibit neurocognitive changes while taking carbamazepine should also be checked for hyponatremia, which is associated with carbamazepine and its analogs oxcarbazepine and eslicarbazepine. At very high levels, symptoms also may include cardiac dysrhythmias, seizures, and respiratory depression.

Carbamazepine levels may be altered by the coadministration of medications that inhibit the metabolism of carbamazepine. Such agents include erythromycin and related antibiotics, valproic acid, cimetidine, propoxyphene, and isoniazid, among other CYP 3A4 inhibitors. Carbamazepine is a powerful CYP 3A4 inducer and thus must be used cautiously and with careful monitoring when combined with other medications metabolized by CYP 3A4. Further, carbamazepine has the ability to lower its own serum level through the process of hepatic enzyme autoinduction. Typically, autoinduction of hepatic enzymes occurs several weeks after initiation of carbamazepine treatment. Many clinicians follow levels over time and adjust the administered dose as necessary to maintain a therapeutic concentration. In malnourished patients or those with low protein due to other medical conditions, it may be advisable to monitor serum albumin levels. A portion of the drug is bound to serum proteins. It is the free (unbound) component that is biologically active. When there are reductions in serum proteins that bind the drug, an adjustment in the dose may be necessary, particularly in patients who show signs of toxicity.

OXCARBAZEPINE. Oxcarbazepine is structurally similar to carbamazepine but has fewer drug interactions and fewer side effects, with the exception of increased frequency of clinically significant hyponatremia. Many clinicians obtain baseline serum electrolytes and repeat this testing as clinically indicated. Therapeutic serum oxcarbazepine levels have not been established. In women of childbearing age, a pretreatment pregnancy test should be evaluated; women should be advised that hormonal contraception may be less effective during oxcarbazepine treatment.

A 58-year-old woman with bipolar I disorder was recently transitioned from carbamazepine to oxcarbazepine due to poor tolerability of carbamazepine. One month after initiation of oxcarbazepine, she and her spouse reported that she was having difficulty with memory and periods of acute confusion. She appeared drowsy in the office and had poor attention. Serum electrolyte evaluation revealed sodium of 118 mEq/L. She was admitted to internal medicine for treatment, and oxcarbazepine was discontinued.

LAMOTRIGINE. Therapeutic serum lamotrigine levels have not been established. Dosing is titrated to clinical response.

LITHIUM. Lithium has a narrow therapeutic index. Consequently, blood levels of lithium must be monitored to achieve therapeutic dosing and avoid toxicity. For acute mania, target serum levels of lithium are in the range of 0.8 to 1.2 mEq/L. Optimum maintenance serum levels may vary from patient to patient, with the goal of achieving a balance between clinical efficacy and tolerability. Many clinicians aim for maintenance levels between 0.6 to 0.8 mEq/L, especially if patients complain of side effects at levels of 0.8 mEq/L or higher. Side effects are dose dependent. Symptoms of toxicity may begin to manifest with serum levels of greater than 1.2 mEq/L and are common with levels greater than 1.4 mEq/L. Older or seriously medically ill patients may show signs of toxicity with levels less than 1.2 mEq/L. With high levels (e.g., >2 mEq/L), consultation with a nephrologist or internist should occur. In patients with high serum lithium levels, dialysis is preferable to reduce lithium levels because prolonged exposure increases the likelihood of irreversible cerebral damage. Symptoms of toxicity include tremors, sedation, and confusion. At higher levels, delirium, seizures, coma, and death may occur.

Steady-state serum lithium levels are achieved after five half-lives, and lithium levels typically reach steady-state 5 days after a change in dosage in patients with normal renal function. Levels are obtained as close to 12 hours after the last dose as possible and are usually measured using samples obtained in the morning before administration of the morning dose (trough level). In cases of suspected lithium toxicity, levels are obtained sooner.

Maintenance levels are checked every 3 to 6 months and sometimes more frequently in patients with compromised renal function, general debilitation, or signs of toxicity. Close monitoring is required for patients who take medications that may alter lithium levels, such as diuretics or certain nonsteroidal anti-inflammatory drugs (NSAIDs).

Baseline pretreatment studies and periodic follow-up tests for lithium should include monitoring of renal and thyroid function. Renal function is monitored using BUN, serum Cr, and a urinalysis. Because lithium commonly affects thyroid function, a baseline screening assessment of thyroid function (TSH) is obtained. These tests are repeated once or twice during the first 6 months of treatment and subsequently every 6 months to every year during ongoing treatment. Clinicians also should obtain thyroid studies in patients taking lithium who develop fatigue or asthenia, cold intolerance, or changes in the skin, voice, or weight (symptoms of impaired thyroid function). Many clinicians measure calcium levels at baseline and every 6 months to 1 year, given the association of lithium treatment with parathyroid dysfunction and hypercalcemia. Also, because lithium commonly produces a mild leukocytosis, a pretreatment WBC is often obtained.

A 48-year-old man with schizoaffective disorder had been stably managed with lithium and risperidone for the past 3 years. He was recently medically hospitalized for evaluation of chest pain. The primary team requested a hematology/oncology evaluation due to concern over his persistently elevated WBC ranging from 12,000 to 16,000/mm^3. Upon medical record review, the consulting psychiatrist noted that prior to the initiation of lithium, his WBC had been within normal limits. The team was advised of this common side effect of lithium for their consideration in formulating the differential diagnosis.

Before the administration of lithium in women of childbearing age, a screening urine pregnancy test should generally be obtained. The use of lithium during the first trimester of pregnancy requires a careful risk/benefit analysis, as there is an increased risk of congenital heart disease with fetal exposure to lithium. Lithium levels should be carefully monitored during pregnancy and after labor. Rapid shifts in fluid volume can give rise to rapid changes in lithium levels during this time.

In patients over age 40 or with known risk factors for cardiovascular disease, a pretreatment ECG is recommended. Many clinicians monitor ECG on a yearly basis; guidelines vary.

VALPROATE. Valproate (valproic acid [Depakene] and divalproex [Depakote]) is used to treat acute mania and for maintenance treatment of bipolar disorder. Therapeutic levels for acute mania are thought to range from 50 to 125 mcg/mL; based upon analysis of clinical trial data, most clinicians aim for a valproate level between 85 and 125 mcg/mL for acute mania. During maintenance treatment, clinicians work individually with patients to achieve a dose that is within a therapeutic range but remains tolerable. Side effects are more common with levels greater than 100 mcg/mL.

Because of the risk of hepatotoxicity and hematologic abnormalities during valproate treatment, baseline LFTs and hematologic measures are advised. Irreversible hepatic failure and agranulocytosis are rare, idiosyncratic effects of valproate; patients should be advised to report immediately for evaluation should they develop concerning symptoms. Hepatic necrosis is rare and is more likely to occur in the very young (younger than 2 years of age) and in individuals taking multiple anticonvulsants. More commonly, valproate may cause an asymptomatic elevation in liver transaminase levels and mild leukopenia or thrombocytopenia. Most clinicians monitor CBC and LFTs every 6 to 12 months during valproate treatment.

Valproate increases the risk of birth defects, including neural tube defects (with rates of 3% to 5%), craniofacial abnormalities, limb malformations, and cardiac defects. A pretreatment urine pregnancy test should be obtained in women of childbearing years. Women should be cautioned to use adequate contraception. Careful consideration of the known teratogenic effects of mood-stabilizing agents is essential when initiating treatment for a woman of childbearing age, regardless of whether or not she is currently pregnant. Given teratogenicity, many clinicians avoid prescribing valproate to any woman who has childbearing potential.

Treatment with valproate may increase serum ammonia levels, even in the absence of LFT abnormalities. It is prudent to obtain an ammonia level in a patient undergoing valproate treatment who presents with altered mental status or lethargy. Acute pancreatitis may also occur but is rare.

Antidepressants

MONOAMINE OXIDASE INHIBITORS. Treatment with monoamine oxidase inhibitors (MAOIs) can cause orthostasis and, rarely, hypertensive crisis as a result of drug–drug or drug–food interactions. Baseline blood pressure measurement should be obtained before the initiation of treatment, and blood pressure should be monitored during treatment as clinically indicated. There are no meaningful blood levels for MAOIs, and direct monitoring of MAOI blood levels is not clinically indicated.

TRICYCLIC AND TETRACYCLIC ANTIDEPRESSANTS. TCAs can affect cardiac conduction. Thus, patients should be screened for a history of cardiac disease or cardiac risk factors that may lead to conduction abnormalities prior to TCA administration. Patients with risk factors for cardiac disease or who are over the age of 40 should have a baseline ECG to rule out existing conduction abnormalities. Heart rate may increase as a result of anticholinergic effects of the medication. In an overdose, a QRS interval of longer than 100 milliseconds may predict the development of seizures and ventricular arrhythmias and is an indication for bicarbonate therapy.

Baseline vital signs with orthostatic measurements should be obtained before the initiation of TCAs, especially in the older adults in whom TCA treatment can significantly increase the risk of hip fracture owing to TCA side effects of orthostasis. Subsequent orthostasis measurements should be obtained to assist with dose titration in this population.

Plasma levels of TCAs may be useful when there is a need to rapidly achieve a therapeutic dose of the medication, when patients need the lowest effective dose (e.g., sensitivity to side effects), when questions exist about a patient’s compliance, and when there is a poor response to a standard dose. Other indications for obtaining plasma TCA levels include concomitant administration of medications that may alter TCA blood levels or the re-emergence of depression in a patient who had an initial therapeutic response to TCA treatment.

TCA levels usually are obtained 12 hours after the administration of a dose. Typically, this is in the morning before administration of the morning dose. Levels are most meaningful when a steady-state has been achieved, at least five half-lives after the last change in dose. Meaningful serum levels have been determined only for nortriptyline (50 to 150 ng/mL), desipramine (>125 ng/mL), and imipramine (total of imipramine and desmethylimipramine [desipramine] >200 ng/mL).

CONCLUSION

An important role of the psychiatric clinician is to maintain vigilance for medical or neurologic conditions that may mimic primary psychiatric disorders and to order or recommend appropriate studies to evaluate for such conditions when indicated. Additionally, the safe provision of psychiatric care often requires evaluating for potential toxicity of certain agents and for the monitoring of particular laboratory studies over a period of time, at regular intervals, depending upon the treatment provided. Whether utilizing laboratory or imaging studies for screening, diagnosis, or treatment monitoring, it is important to judiciously select tests and carefully interpret results, acknowledging that no test has perfect sensitivity, specificity, and/or positive or negative predictive value. It is preferable to select and order tests based on the ability of the test results to change management rather than to routinely order a host of screening tests that may be costly and unlikely to meaningfully impact patient care.

7.7 Principles and Applications of Quantitative Electroencephalography in Psychiatry

LESLIE S. PRICHEP, PH.D.

DEDICATION

This chapter is dedicated to the legacy of E. Roy John, Ph.D., whose pioneering innovation and insights into brain function are at the foundation of the work presented herein and have significantly advanced the clinical utility of quantitative electrophysiology. Dr. John was a co-author in prior editions of this chapter.

This section is intended to provide a primer for the underlying neurophysiologic theory, basic concepts, and nomenclature of quantitative electroencephalography (qEEG) and an overview of clinical applications of qEEG in neuropsychiatry. This chapter reviews the signal processing methods used to extract quantitative features from the raw EEG, convert them to standard scores, display them as qEEG-based tomographic brain images, and use them as input to classification algorithms, which together reduce the profuse electrical phenomenology of the brain to more objective, anatomically localized, and clinically useful descriptors of abnormal brain function. A clinically oriented section describes statistical methods used to seek distinctive patterns or profiles of qEEG features for patients with specific disorders. This section (1) explains the use of machine learning derived statistical classifier methods for identification of distinctive profiles of abnormality for groups of patients diagnosed using the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) (edition according to time the patients were tested); (2) gives examples of the performance and clinical utility of qEEG-based classification algorithms; (3) explains cluster analytic methods used to identify pathophysiologic heterogeneity (subtypes/phenotypes) within clinically homogeneous cohorts of patients with the same DSM diagnosis; (4) summarizes applications of the performance and clinical utility of qEEG subtyping methods in clinical optimization of treatment decisions; and (5) describes the uses of qEEG source localization in expanding the understanding of underlying pathophysiology of disorders. Finally, research on the neurophysiology of anesthesia and information processing is integrated to review the current understanding of brain mechanisms that bind sensations, emotions, motivation, and memories into perceptual experiences that become the momentary content of conscious awareness, to describe processes that mediate how affect and mood modulate subjective reactions to these experiences, and to explore how dysfunction of these systems can contribute to psychiatric illnesses.

FROM EEG TO qEEG

Background and History

In 1928 the human EEG was first recorded by the German psychiatrist Hans Berger, who believed that its study would reveal information about psychiatric disorders and cognitive functions and revolutionize the practice of psychiatry. However, for over half a century, its major clinical application was in the arena of detection and treatment of seizure disorders. By 1938, Berger's discovery had aroused so much interest among neurologists and psychiatrists that an International Federation of Electroencephalographers agreed upon a standard method for positioning 19 electrodes upon the head, the International 10/20 Electrode Placement System, used to this day. After extensive neuroanatomical studies, this proportional method locates each electrode approximately above a specified functional region or Brodmann cytoarchitectural area of the brain independent of the absolute size of the head, defining positions as percentages of arcs measured on the head. The locations of this system are shown schematically in Figure 7.7–1.

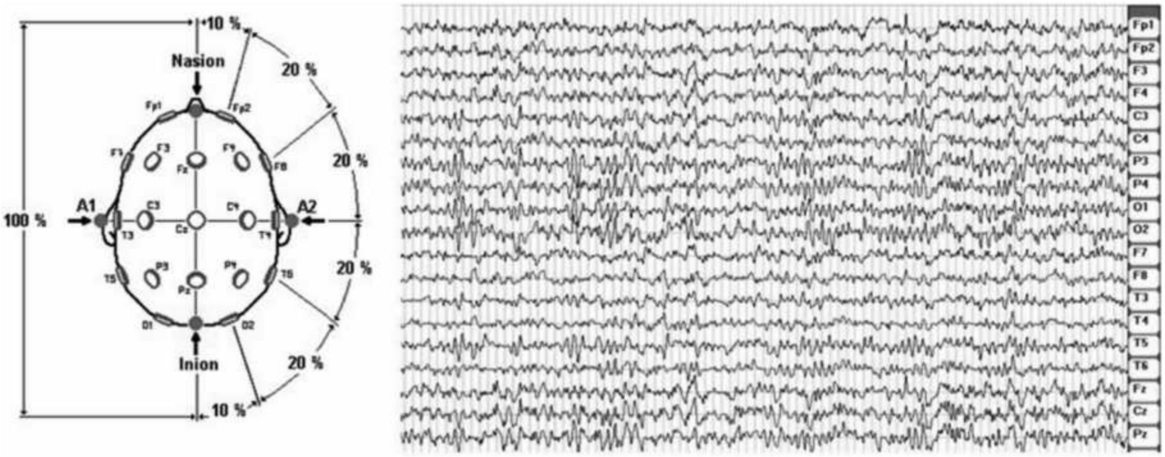

FIGURE 7.7–1. (*Left*) A schematic of the standardized electrode positions of the International 10/20 Electrode Placement System that locates electrodes at distances proportional to 10% or 20% of the circumference and several arcs measured from side to side and from nasion to inion on the head, treated as an ellipsoid is shown. (*Right*) Eight seconds of EEG data from the screen of the computer, showing EEG data from each electrode location referenced to linked ears.

Contrary to Berger’s hopes, insights from the EEG into the underlying causes of psychiatric disorders or how to improve the clinical treatment of psychiatric patients were not readily evident. However, its utility for the detection, diagnosis, and treatment of a wide variety of neurologic disorders became rapidly apparent. Using visual examination of oscilloscopic analog recordings of voltage fluctuations recorded from the scalp, generations of electroencephalographers who were focused primarily on neurologic illnesses visually examined tracings and sought to identify distinctive wave shapes and spatial patterns related to their clinical experience. After the introduction in around 1970 of computer methods to record and analyze the EEG with readily available digital computers, digital electroencephalography (DEEG) began gradually to replace the conventional analog recording instruments, with great advantages of compact and economic digital media replacing voluminous paper recordings.

qEEG was introduced in the next decade. qEEG augmented visual analysis by computation of the power spectrum to analyze the EEG oscillations from each region on the scalp, replacing tracings with an objective set of numbers that quantified the distribution of power as a function of frequency. During the next 35 years, psychiatrists and psychologists began to study the power spectrum, and the relevance of qEEG to the study of psychiatric and neuropsychiatric disorders, as well as of brain functions and psychophysiological processes, became more and more evident. qEEG measures were expressed as numbers that quantified features extracted from recordings at each electrode position, such as the absolute amount of power within specified frequency ranges or "bands," the percentage of the total power that falls in each band (relative power), the synchronization or symmetry of such measures between corresponding or "homologous" regions on the two hemispheres, and the relationships of electrical transactions among regions between and within each hemisphere ("connectivity"). Over the last decade, methods derived from signal processing advances and analytic methods (e.g., from genomics, proteomics, and machine learning [ML]) were also applied to the EEG, yielding further feature descriptors and expanding the underlying processes that could be described. qEEG methods have yielded objective data about brain electrical correlates of information processing, cognitive processes and cognitive impairments of aging and in childhood, and alterations of consciousness such as during anesthesia and sleep, as well as in psychiatric illness and revealed distinctive qEEG effects of various classes of psychotropic drugs. Such research provided important insights into neurophysiologic processes mediating attention, sensation, perception, behavior, and cognition.

Distinctive patterns of qEEG features have been described for a wide variety of developmental, neurologic, and psychiatric disorders, akin to the clinical significance of particular abnormal rhythms and patterns in the ECG. Some of these findings have been reported from the relational database of the Brain Research Laboratories of the Department of Psychiatry at the New York University School of Medicine, one of the largest qEEG quantitative electrophysiologic databases in the world, which contains "raw" unprocessed EEG and event-related potential (ERP) recordings, extracted features and clinical data from over 15,000 examinations of patients and normal functioning individuals, collected between 1980 and 2015. This database includes EEG and multimodal evoked related potential (ERP) recordings from patients with many different diagnostic conditions, including attention-deficit/hyperactivity disorder (ADHD), alcoholism, autism spectrum disorder (ASD), and Asperger syndrome, cognitively impaired older adult patients (with a staging of cognitive deterioration ranging from mild to severe in Alzheimer-type dementia, AD), depression, drug dependence, intractable chronic pain, learning disabilities, obsessive-compulsive disorder (OCD), schizophrenia, stroke, tinnitus, and traumatic brain injury (TBI). Also included are data from patients in coma and persistent vegetative state (PVS), from patients undergoing many different neurosurgical and cardiovascular surgical procedures using a wide variety of anesthetic agents, and from healthy, normally functioning children and adult normally functioning control subjects. These records were stored digitally in their original, unprocessed form, which could be readily retrieved for analysis with new mathematical algorithms as they are developed or to test new theoretical hypotheses and constitute a major scientific resource. Multiple collaborative projects with leading research groups in many countries steadily dynamically increased the scope of this database.

For several of these disorders, profiles of deviant qEEG findings have been found that are either distinctive for patients diagnosed with a particular DSM disorder, predictive of the evolution of the condition, or indicative of differential response to treatment, discussed in more detail below. Certain deviations from this baseline have been found to occur invariantly and reversibly with loss and return of awareness during anesthesia or coma that offer insights into brain mechanisms related to the production and maintenance of consciousness, further discussed later in this section.

NEUROMETRIC qEEG: HOMEOSTATIC REGULATION OF THE EEG FREQUENCY SPECTRUM

A major enhancement of the clinical utility of qEEG derives from the well-confirmed discovery and recognition that the electrical activity of the brain of a person of any age, alert but at rest in a quiet, dimly lit environment, is dynamically regulated by an anatomically extensive, genetically based neurophysiologic homeostatic system. This power spectrum is extremely stable and highly replicable, distinctive for each brain region in a healthy, normally functioning individual, and independent of cultural, ethnic, or racial factors. Therefore, this predictable, known power spectrum can be used as a normative baseline that specifies the expected electrical activity of the healthy, normally functioning human brain across the human life span. The interactions between different brain regions, such as synchronization or coherence (nonrandomly phase-locked oscillations) and power symmetry between corresponding locations within and between the two hemispheres, are similarly regulated.

If the procedures described below are followed, then deviations from these norms can be described as standard scores, providing a reliable and objective metric for abnormalities of brain electrical activity. Further, since all features are expressed in the same units, they can be combined and expressed as multivariate descriptors of brain function. Like the ECG, deviations from the normal pattern of electrical activity are indicative of pathophysiologic processes and may have diagnostic implications and utility. Particular profiles of deviant standard scores have been found to be reliably correlated with certain categories of brain dysfunction or disorders or with positive as well as negative responses to specific treatments or evolution of the illness.

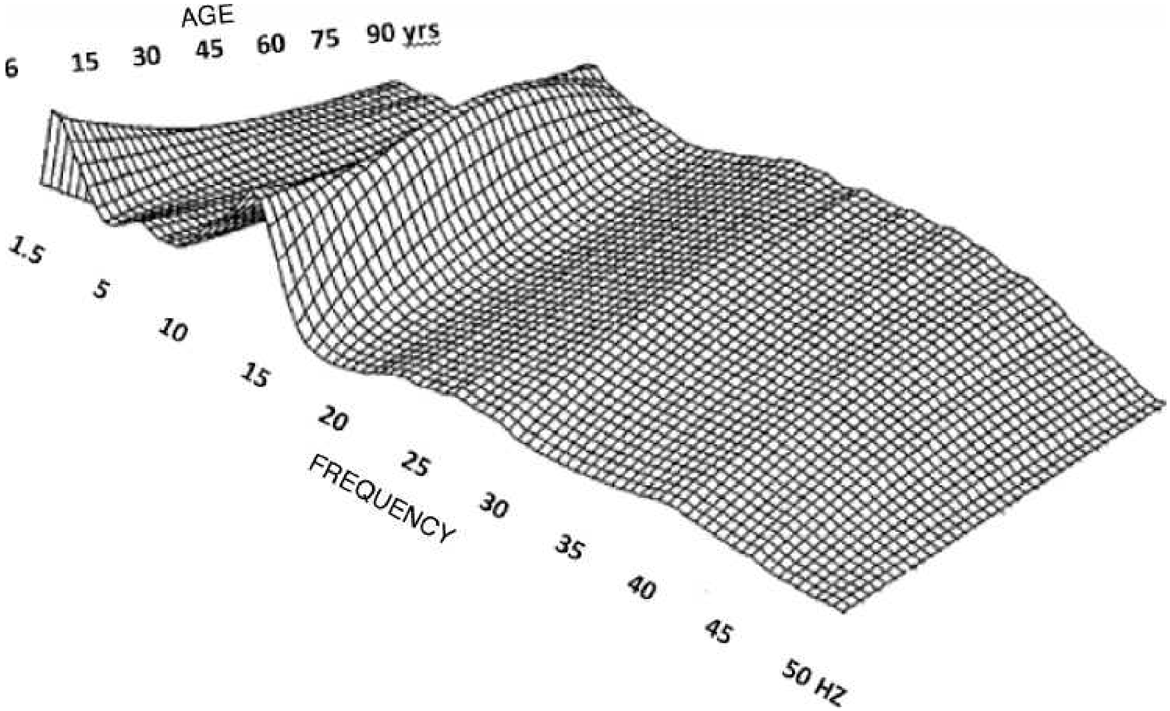

FIGURE 7.7–2. Schematic of the normative (*N* = *456*) EEG "relative power" ground state of the brain, for the 10/20 electrode at the midline parietal region (Pz) location, represented as a three-dimensional surface: *X-axis*, frequencies in 0.39 Hz intervals from 1.5 to 50 Hz; *Y-axis*, age shown in 1-year intervals from 6 to 90 years; and *Z axis*, magnitude of percent (%) power of the EEG at each frequency, 0% to 100%, represented by the height of the surface. Each "slice" of the image from left to right side of the image is the normal frequency composition of the EEG for that age. As you go from front to back of the image you are viewing the composition of frequency stacked across all ages shown. Note also that while shown here in one-year intervals, the actual normative regression equations are for continuous age, so that each individual is compared with norms for their exact age.

For each of the classes of qEEG features, the distribution of electrical measures within different portions of this range has conventionally been evaluated in so-called "wide-frequency bands," namely, the delta (1.5 to 3.5 Hz), theta (3.5 to 7.5 Hz), alpha-1 (7.5 to 10 Hz), alpha-2 (10 to 12.5 Hz), beta (12.5 to 25 Hz), and gamma (30 to 50 Hz) frequency bands. It is noted that the alpha, beta and gamma, and other bands can also be further divided. These seemingly arbitrary definitions of frequency bands, initially made by electroencephalographers on the basis of repeated visual inspection of apparently independent variations of rhythmic oscillations, correspond to the findings of independent sources of variance in the digitized EEG subsequently obtained by computerized principal component analyses. In current qEEG practice with advances in signal processing methodology and instrumentation, there is a steady expansion of the number of electrodes to as many as 256 positions on the head and of the frequency range to examine much faster oscillations as high as 1 kHz (1,000 counts per second) and a shift toward the use of the so-called very narrow band (VNB) (0.39- or 1.0-Hz divisions) spectral analysis, which has enabled the use of source localization and expanded exploration of the underlying pathophysiology.

Normative values of these various qEEG descriptors across a wide age range (6 to 90 years) have been established and repeatedly independently replicated in multiple countries, indicating that they are independent of race or ethnicity. High test–retest reliability has also been published. This regulation reflects activity within and interactions among many brain regions, reflected in local field potentials (LFPs) as well as the spontaneous EEG, mediated by many different chemical neurotransmitters whose synthesis and metabolism are similarly dynamically regulated and define the ground state of the brain. In Figure 7.7–2, the evolution of the EEG ground state for relative power (percent of total power at each frequency) at the midline parietal electrode (Pz) is depicted as a three-dimensional developmental surface; an analogous surface has been computed for the ground state of each electrode in the 10/20 system. While not shown here, normative values have been extended to the first year of life.

Step C, not shown in this figure is the combination of selected univariate *Z*-scores into multivariate estimators (Mahalanobis distances).

The concept of the ground state of the brain being an anatomically extensive, genetically based neurophysiologic homeostatic system is consistent with current hypotheses of the default mode network (DMN). The default network or DMN can be defined as the “brain system,” which is active when individuals are not focused on or receiving input from the external environment. The scientific literature describes the anatomy of the DMN as involving a distributed set of regions, including, in particular, the medial frontal regions, the inferior parietal lobule, the hippocampus, the medial temporal lobe, and the posterior cingulate cortex. The interaction between the regions involved in the DMN has been described as hubs, each including interactions between subsystems that are highly correlated with each other and weakly correlated with the others. Further, just as deviations from the age-expected normal values of the ground state have been demonstrated to be characteristic of different psychiatric disorders, the DMN has been postulated to be abnormal in many psychiatric states, including autism, schizophrenia, ADHD, PTS, and AD, all of which can be thought of as conditions associated with cognitive dysfunction in domains linked to the DMN, supporting the link between the ground state and DMN.

STEPS IN NEUROMETRIC qEEG ANALYSIS

qEEG Features

“Neurometric” qEEG analysis refers to the computer extraction from the visually or computer-edited, artifact-free EEG, recorded from 19 scalp electrodes located by the 10/20 system, of a large number of quantitative “univariate” features that assess different attributes of the electrical activity of the brain, and compared to age expected normal values. The steps presented in Figure 7.7–3 describe in detail the two main steps in neurometric analysis. The first step, seen in Panel A of the figure, shows how variables are transformed to obtain more Gaussian distributions using $\log_{10}$ transforms. The ability of these transforms to improve the Gaussianity of the distributions has been confirmed. Some investigators have more recently suggested different transforms, which may further improve the Gaussianity of the features, but such changes do not result in a significant change in feature values.

The second step is the computation of the *Z* score for the difference between age-predicted normative value (using age-regression) and the value obtained in the patient, which permits the estimation of the probability that such a value might be obtained by chance from a healthy peer’s exact age of the patient. As can be seen in Panel B of the figure, the mean and standard deviation of the normal population for the age of the patient is used to derive the *Z* score of the patient. The use of *Z* scores for all features validates the use of parametric statistical methods for further analysis. This method is standardly used by clinical laboratories to report findings from blood tests.

Conversion of all variables to the common metric of probability enables multivariate combination of variables, with initially different physical dimensions (e.g., uV for absolute power, percentage for relative power, and correlation for coherence), into a multivariate composite feature or brain state vector, to obtain a quantitative estimate of the overall severity of dysfunction within a region, a set of regions, or between regions within a measure. One such multivariate method used in Neurometrics is the Mahalanobis distance. Computation of the Mahalanobis distance removes the contribution of intercorrelations among the set, providing a corrected estimate of the overall abnormality of the combined set. Such multivariate descriptors can be thought of as characteristics of the system.

A particularly informative use of the Mahalanobis distances is in developmental disorders, in which deviations can be characterized as “maturational lags” or “developmental deviations.” Maturational lags are those multivariate patterns of brain function that would be normal if the child was younger. That is, such activity does occur in normal brain function but is not age-appropriate. On the other hand, developmental deviations are multivariate patterns that would not be considered normal regardless of the age of the individual. Such characterization of dysfunction can have a significant impact on the prognosis and treatment of the individual. Unpublished findings using this characterization of abnormalities suggested that those who responded to a pharmacologic intervention were more likely to have been described as having developmental deviations, whereas those with abnormalities best described as maturational lags were likely to become more normal over time without such intervention.

Reporting Results

In analyses of individuals, extracted features include an extensive set of features, each expressed as deviations relative to the age-appropriate normative values. These results can be reported in numerical tables, with highlighting of statistically significant results. For each of the 19 monopolar derivations, with the steps described above, the following measure sets are derived from the frequency spectra: the absolute power (uV2), relative power (percent), and mean frequency (the point above and below which half of the power falls in a band) are computed for the delta (1.5 to 3.5 Hz), theta (3.5 to 7.5 Hz), alpha (7.5 to 12.5 Hz), beta (12.5 to 25 Hz), and gamma (30 to 50 Hz) frequency bands and the total spectral power. Changes in spectral power can reflect changes, including those related to neurochemistry, oxygen flow, glucose metabolism, brain edema, and other conditions. In addition, connectivity between and within hemispheres is derived, including measures of coherence (synchronization), phase, and asymmetry (power ratios) in all frequency bands computed for all electrode pairs within and between hemispheres, reflecting disruption in neuronal transmission between brain regions. These same measures are computed for bipolar derivations of each electrode versus every other electrode within each hemisphere (connectivity). Measures of signal “complexity” including entropy, fractal dimension and others are also computed reflecting disruption of neural networks.

Interpolated topographic *Z*-score images can depict the statistical significance of local deviations relative to age-expected normal values for all univariates in each measure set as well as for a selected set of multivariate measures. Such maps are color-coded using a palette in which different hues represent the probability of the findings at each brain region. Because each *Z* value has a known statistical probability associated with it (e.g., $Z = \pm 1.96$ has $P < .05$), the results of such analyses are objective as well as self-interpreting. Figure 7.7–4 shows a sample of group average qEEG Z images (nose up, left hemisphere on the left) for different populations of psychiatric patients in each row. Each column represents a selected measure set. Significant local deviations from age-expected values can be seen as colored regions on the maps. In the color-coding for significance in this figure, the center of the scale, black, indicates no deviations from expected normative values. Moving up the scale through red to orange and yellow goes toward significant excess of the measure and down through blue to light green indicates a significant deficit of the measure. Looking at the top row on the left of this figure, all maps appear dark to black, showing no deviations from age-expected values in this large group of normal adults. On the other hand, in all other rows, significant excesses and deficits can be seen in all groups, and differences in the patterns of these deviations are also evident between the groups.

It is interesting to note that the progressive magnitude of abnormalities can be seen when comparing the images from the mild cognitive impairment (MCI) and Alzheimer disease (AD) groups (especially in relative power in theta, relative power in beta, and mean frequency of the total spectra, columns two, three, and five of the right panel). Also noted are the similarities between the schizophrenic patients off medication for 90 days and those on medication at the time of the test (bottom two rows in the left panel), suggesting the presence of the medication. The presence of distinctive patterns of qEEG abnormalities and differences between groups will be further discussed in more detail below.

Measures of connectivity have been increasingly demonstrated to be of importance in the description of brain dysfunction in mild traumatic brain injury (mTBI), concussion, postconcussive syndrome, post-traumatic stress disorder (PTSD), autism, and AD. Figure 7.7–5 shows an example of the images for coherence connectivity measures in the theta frequency band in a 64-year-old with early signs of cognitive decline. Each electrode location shows the results for the coherence between the labeled region and each other regions in the labeled band (Delta, Theta, Alpha, Beta, Beta2). The significance of the hypo- or hypercoherence is color-coded.

In addition to the conventional measures described above, the same methods have been extended to describe the complexity of the EEG signal measures of complexity, including chaotic/fractal measures, as well as theory-based measures of entropy and measures of mutual information. The complexity of the EEG signal reflects the disorganization of neural networks. These measures have been shown to be particularly important in the study of anesthetic affects (loss and return of consciousness), TBI, and PTSD and expand the measure of disturbances in the EEG signal to include nonlinear measures beyond the frequency domain.

HOMEOSTATIC SYSTEM GENERATING AND REGULATING THE EEG

The neuroanatomy and neurochemistry of the homeostatic system generating and regulating the EEG are schematized in Figure 7.7–6. The alpha rhythm arises from pacemaker neurons in the thalamus, which have an intrinsic oscillatory rhythm in the EEG alpha frequency range (7.5 to 12.5 Hz) and synchronize similar activity from neurons dispersed throughout the neocortex. When “instructed” by the cortex, the nucleus reticularis (encapsulating much of the thalamus like the skin of a pear) exerts differential GABAergic influences that hyperpolarize these pacemakers, slowing their frequency down to as low as 5 or 6 Hz (cycles per second) to enter the theta range.

When arousing afferent input reaches the midbrain reticular formation, and specific sensory thalamocortical relay (TCR) nuclei of the thalamus, cholinergic outflow from the ascending reticular activating system (ARAS) is sent to the nonspecific nuclei of the thalamic diffuse projection system and to the nucleus reticularis, antagonizing the inhibitory modulation of γ-aminobutyric acid (GABA), depolarizing pacemaker neurons, and allowing them to accelerate their slowed oscillations even into the 12 to 15 Hz range, usually referred to as beta. These interactions can serve to focus attention by modulating the excitability of TCR gates.

FIGURE 7.7–4. Group average topographic images of selected neurometric variables (columns) across different clinical populations (rows). Columns, left to right: (1) absolute power (microvolts squared) in the alpha frequency band; (2) relative power (%) in the theta band; (3) relative power (%) in the beta band; (4) interhemispheric coherence (% synchronization) in the alpha band; and (5) mean frequency of total spectra of the EEG (Hz). (*Left*) Row 1, Normal individuals not used to construct the norms (*n* = 181); Row 2, Unipolar patients in depressed state (*n* = 89); Row 3, Bipolar patients in depressed state (*n* = 38); Row 4, Chronic schizophrenic patients, nonmedicated >3 months (*n* = 26); Row 5, Chronic schizophrenic patients, currently on medication (*n* = 93). (*Right*) Row 1, Drug-free baseline data in obsessive-compulsive disorder (OCD) patients who go on to be selective serotonin reuptake inhibitor (SSRI) responders (*n* = 37); Row 2, Drug-free baseline data in OCD patients who go on to be SSRI Nonresponders (*n* = 18); Row 3, mild cognitively impaired (MCI) older adult patients with a GDS staging of 3 (*n* = 64); Row 4, Alzheimer disease (AD), with GDS staging of 4 to 6, (*n* = 108); Row 5, Children with attention-deficit/hyperactivity disorder (ADHD) (*n* = 100). The color scale is proportional to the significance of the deviation from age-expected normal values, with black, no departure; blue to light green, deficits; and red to yellow, excesses. Statistical significance of entry for any group can be estimated by multiplying the value of the indicated hue on the *Z* score color bar by the square root of the group *N*. (See eBook for color image.)

Oscillations in the beta range (12.5 to 25 Hz) and in the gamma range (30 to 50 Hz) arise in the EEG to reflect thalamocortical and corticocortical transactions concerned with information processing and consciousness. Delta rhythms (0.5 to 3.5 Hz) arise from neurons in the cortex and often reflect functional deafferentation or neuropathologic influences such as ischemia or increased intracranial pressure but can be depressed by certain pharmaceutical agents or substance abuse. Hypothetical functional roles and processes attributed to regions in this diagram will be discussed further in the text.

Additional EEG rhythms arise from the activation of the dorsal striatum (sensorimotor integration) and ventral striatum and amygdala (emotional state and affect), interacting with major components of the limbic system for storage and retrieval of memories. Activation of this system results in outflow via the nucleus medialis dorsalis of the thalamus and the anterior and posterior cingulate cortices, of rhythmic theta waves (3.5 to 7.5 Hz) carrying phase-locked gamma oscillations (30 to 50 Hz) reflecting retrieval of memories via the hippocampus. This is discussed in further detail later in this section.

Multivariate features

Rescaling all neurometric features as *Z* scores, providing a common dimension proportional to probability, allows any selected set of qEEG measures to be compressed into a multivariate estimate of the total overall abnormality across the set. With one such method, the Mahalanobis distance (see above), the contribution of intercorrelations among the set is removed, providing a corrected estimate of the overall abnormality of the combined set.

With Mahalanobis distances, results of a qEEG evaluation can be represented quantitatively in a brain signal space. The length of the multivariate vector corresponds to the severity of the deviation of the patient's brain electrical activity from the origin defined by age-appropriate normative values, and its orientation in the physiologic space represents the quality or nature of the pathophysiology. By this representation of patients with different diagnoses and normal individuals as points in the signal space, two questions relevant to diagnosis can be answered quantitatively and will be addressed later in this section: (1) Can stepwise classifier functions (such as discriminant analysis) be derived that identify electrophysiologic biomarkers that separate patients with different diagnoses from each other or from normal individuals? (2) Can cluster analytical methods reveal subtypes/phenotypes with distinctive qEEG profiles but with the same clinical diagnosis, unmasking pathophysiologic heterogeneity in that diagnostic category?

FIGURE 7.7–5. Each component image (individual head map with nose up and left on the left) shows the results for the coherence between the labeled region and all other regions in the labeled band (in this case the theta frequency band), color-coded by significance level using the Z-scale shown. Regions in black are within normal limits, all colored regions are significant at $P < .05$ with the extremes at $P < .001$. The top left image shows the connectivity between the left frontopolar regions (FP1) and all other regions in the theta band, a band that has been shown in the literature to be correlated with degree of cognitive decline in older adults. It can be seen that there is a significant hypercoherence between these regions and both short and long-distance relationships on the left hemisphere and midline regions. This hypercoherence is also reflected in the coherence between FP1 and the left central (C3), left parietal (P3), and midline parietal (Pz) regions. This hypercoherence between frontal and more distant regions in a patient with early cognitive decline might serve as a baseline for a trajectory of increasing abnormality when tracked longitudinally in this patient. (See eBook for color image.)

qEEG Source Localization Tomographic Brain Images

A powerful expansion of the contribution of qEEG to the understanding of the underlying pathophysiology of neuropsychiatric disorders and the clinical utility of qEEG has been achieved over the past decade by the development and application of source localization analytics. qEEG low-resolution source localization methods perform the computation of an "inverse solution" to localize the mathematically most probable intracranial sources of the scalp-recorded EEG signal. With such methods, voltages or *Z*-scores of qEEG measurements from the scalp can be imaged, providing three-dimensional brain images that have been demonstrated to be coregistered with other neuroimaging methods. The standardized electrode positions of the proportional 10/20 system are placed in geometrical registration with a proportional Probabilistic MRI Brain Atlas, constructed at Montreal Neurological Institute based upon the average magnetic resonance imaging (MRI) anatomy of 300 normal brains. Referring to the computed sources to an average MRI, atlas averts the need to obtain an MRI of the individual patient. The positions of sources at any EEG frequency are depicted upon images of transaxial, sagittal, or coronal slices from the MRI Atlas, with each voxel color-coded in hues that quantify the deviation in each voxel of the computed source from the expected age-appropriate normative value, as in neurometric qEEG. There are two source localization methods that implement voxel norming, Variable Resolution Electromagnetic Tomographic Analysis (VARETA) and standardized Low-Resolution Brain Electrical Tomography (sLORETA); examples using these methods of source localization will be given below (see Figs. 7.7–7 to 7.7–10). The anatomical accuracy of these brain images computed from the qEEG has been repeatedly confirmed by coregistration studies using MRI, functional MRI (fMRI), positron emission tomography (PET), and single-photon emission computed tomography (SPECT).

Neurometric qEEG source localization provides a unique, innovative technology for functional brain mapping, since no other functional imaging method, neither fMRI, PET, nor SPECT, provides access to age-appropriate normative voxel data and only electromagnetic data (EEG or magnetoencephalography [MEG]) has the time resolution in milliseconds, allowing more precise identification of neuronal processes. This method provides the further advantage of the ability to obtain accurate functional brain images with economical and portable equipment which can be used at the point of care without the need for movement restraint within the equipment, camera, or imposition of a burden of radiation. It should be noted that advances in this method allow real-time imaging of sources, which has many interesting possibilities for unique ways to study the potential underlying pathophysiology of psychiatric disorders.

FIGURE 7.7–6. Circuits serving a major role as generators of indicated electroencephalogram (EEG) frequency bands, interrelationships, and mediating neurotransmitters proposed to comprise the homeostatic system regulating the EEG ground state of the brain. Salient hypothesized functional roles have been assigned to regions and putative transmitters assigned to relationships indicated by arrows: ACh, acetylcholine; DA/DA2, dopamine; Ga, γ-aminobutyric acid; Gl, glutamine; 5HT, serotonin; "+," excitatory actions; "-," inhibitory actions. A more complete explanation of this figure can be found in the text. In brief, pacemaker neurons in the thalamus generate an intrinsic oscillatory rhythm in the EEG alpha frequency range (7.5 to 12.5 Hz) propagated to the cortex that can be slowed into the theta range (6 to 7 Hz) by GABAergic influences from the nucleus reticularis, tending to close thalamic gates to the cortex. Incoming sensory information is transmitted by an "exogenous system" via thalamocortical relay (TCR) neurons to the cortex and also enters the midbrain, from which cholinergic arousal influences arise to antagonize γ-aminobutyric acid (GABA) and accelerate the EEG rhythms, opening the thalamic gates, and serving to focus attention. Oscillations in the beta range (12.5 to 25 Hz) and in the gamma range (30 to 50 Hz) reflect

> thalamo–cortical and cortico-cortical information processing. Delta rhythms (0.5 to 3.5 Hz) arise from neurons in the cortex and often increase with neuropathology but can be depressed by substance abuse. Afferent input also activates the dorsal striatum (sensorimotor integration) and ventral striatum, and amygdala (emotional state and affect), interacting with major components of the limbic system for storage and retrieval of memories. Readout from this "endogenous system" results in outflow via the nucleus medialis dorsalis of the thalamus and the anterior and posterior cingulate cortices, of rhythmic theta waves (3.5 to 7.5 Hz) carrying phase-locked gamma oscillations (30 to 50 Hz) reflecting retrieval of memories via the hippocampus. Thus, theta rhythms in the EEG can arise from two quite different causes.

Selection of Anatomical Regions of Interest

Since the statistical significance of deviations from expected normative brain electrical activity can be quantitatively encoded for every voxel within a source image, this input can be used to quantify the significance of deviations for specified anatomical regions of interest (ROIs), allowing the evaluation of the maximum abnormalities in the brain regions of an individual patient. This can be done in a variety of ways. One method maps sets of voxels that are within specific anatomical regions (using an atlas such as Talairach), quantifying and displaying the mean, median, or some percent of significant voxels in the region. Another way to select ROIs can be done by search algorithms that can be conceptually understood as methods to systematically remove from the three-dimensional representation all voxels that have an abnormality less than some selected threshold, for example, the $P < .05$ level ($Z = \pm 1.96$). The remaining voxels will lie within some three-dimensional region within the brain, which an algorithm automatically identifies from the coregistered corresponding anatomical neurosurgical stereotaxic atlas. In this way, ROIs are defined by the significance of deviations rather than anatomical localization. A numerical estimate of the degree of severity of the abnormality can be calculated, for example, by integrating the Z-scores of all voxels within the volume of the ROI, thus defined or counting the number of voxels above the threshold. These methods for quantifying abnormalities could be applied to the evaluation of treatment efficacy, whereby the magnitude of the abnormality before and after treatment is compared. Other methods for statistical analysis of source images include statistical probability mapping (SPM) or nonparametric statistical mapping (SnPM) as used in other brain imaging methods, especially fMRI.

FIGURE 7.7–7. Three-dimensional low-resolution electromagnetic tomographic analysis (LORETA) image of a "dissolved brain" of a patient with AD, after removal of all voxels with a *Z* score less than 3.29 ($P < .001$). The maximum theta excess (*dark red shading*, 4.3 Hz) relative to age-expected normal values is in the hippocampal and parahippocampal regions, while the frontal cortex (Brodmann area 27) reveals a minimum beta deficit (*blue*, 17 Hz). (See eBook for color image.)

Figure 7.7–7 presents an image of the brain of a patient with AD after all voxels with a *Z*-score less than 3.29 ($P < .001$) have been removed from the brain volume. It can be seen in this figure that the area of maximum abnormality relative to age-expected normal voxel values is in the hippocampal and parahippocampal regions.

Brain ROIs identified by neurometric source imaging, scaled for degrees of abnormality quantified by deviation from norms or alteration of function relative to some reference state, can be used as an adjunct to diagnosis, the selection of treatments, evaluation of bioavailability, and pharmacodynamic assessment of efficacy or even in drug development research. ROIs thus identified might then be interrogated by a noninvasive assay using Magnetic Resonance spectroscopy (MRS). MRS already has the capability to quantify the concentration of a steadily increasing number of brain metabolites, neurotransmitters, and critical ionic electrolytes. Such multidisciplinary assessments might eventually become routine in evidence-based personalized psychiatric practice.

CLINICAL APPLICATIONS OF qEEG DEPARTURES FROM GROUND STATE OR DEFAULT MODE NETWORK

Psychopathology: qEEG Biomarkers of Diagnoses

Deviations from normative values imply dysregulation (local and network) that may have functional and treatment implications. In numerous peer-reviewed articles, there is evidence of the high proportion of psychiatric patients in any diagnostic category who consistently display significant deviations from the expected normative qEEG values. This is clearly shown in Figure 7.7–4 for large populations of many different diagnostic groups. Many of the articles present evidence that these profiles are sufficiently distinctive not only to indicate the most probable DSM diagnosis for an individual patient but, in some instances, also can be used to predict differential responses to treatments or different evolution of illness; reviews of the abundant relevant literature are available. It should also be noted that the degree of dysfunction, such as the progressive stages of dementia, can be accurately reflected in the qEEG, demonstrating that increasing qEEG abnormality is correlated well with an increasing degree of cognitive impairment. Thus, qEEG can represent a biomarker, be useful as an adjunct to diagnosis and staging, as well as to aid in the optimal selection and objective evaluation of treatment and treatment response. An example of such, the relationship between the degree of cognitive decline and magnitude of qEEG abnormalities, can be seen in Figure 7.7–4, comparing MCI (third row on the right panel) to AD (fourth row on the right panel), especially as seen in increased excess of relative power in the theta band (second column), an exaggerated deficit of relative beta activity (third column), and significant slowing of the mean frequency of the spectra (fourth column).

If the abnormal qEEG features detected in each member of a group of patients with different DSM-diagnosed disorders are represented in multivariate dimensions, then they can be envisaged as swarms of points (features) dispersed in a multidimensional brain electrical signal space. To the extent that particular profiles of qEEG abnormalities (sets of features or biomarkers that covary with the disease state) are in fact distinctive for patients with one specific symptomatic, DSM-based disorder, patients with the same diagnosis would be expected to lie close together within such a swarm in a region of the signal space, while patients with different DSM diagnoses would constitute swarms in different regions. This concept is shown schematically for patients with disease X and patients with disease Y in Figure 7.7–11.

FIGURE 7.7–9. Source localization (sLORETA) images for group average voxel z-scores for ROIs in the band 5.46-9.36 Hz for the pain population ($N = 77$), shown for a single axial, sagittal, and coronal MRI level (−41, −29,13). The images are color-coded for significance of difference according to the color scale (below figure), where extremes of the color scale are $P < .01$. Overactivation is shown in red/yellow and deactivation in blue/aqua (none seen in this image). (See eBook for color image.)

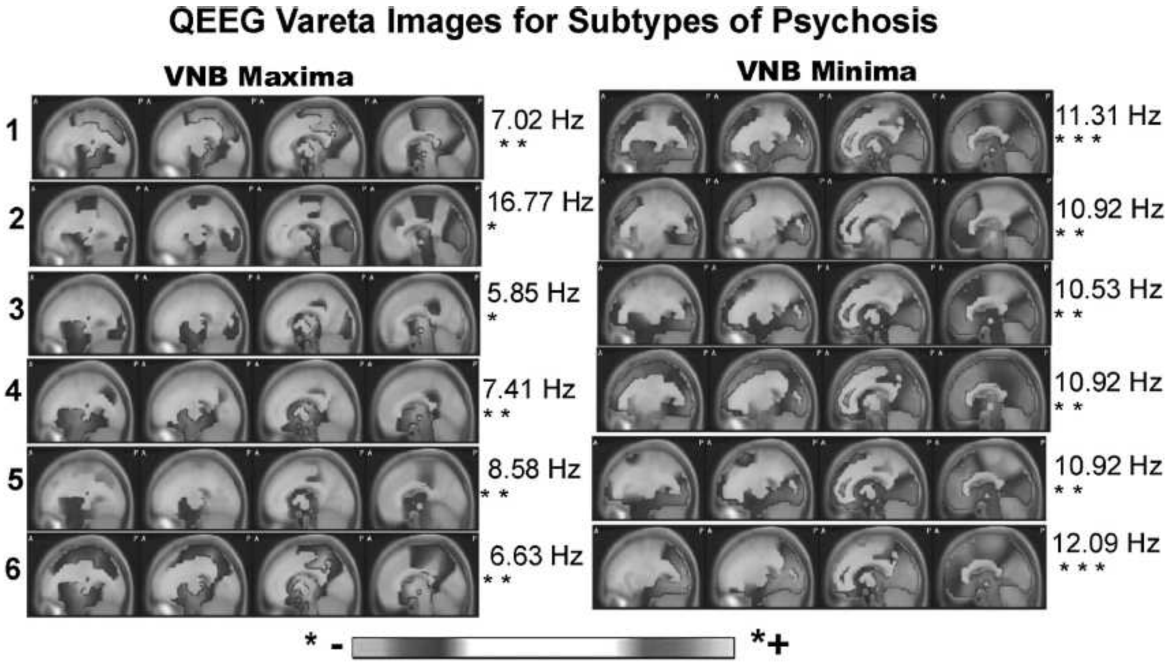

FIGURE 7.7–10. From top to bottom, each row depicts group average quantitative electroencephalography (qEEG) variable resolution electromagnetic tomographic analysis (VARETA) images of selected sagittal slices from the six subtypes (1 to 6) of psychotic patients identified by cluster analysis of a population of 377 psychiatric patients, all of whom were psychotic. Each cluster contained patients who had received a variety of fourth revised edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR)/tenth edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) diagnoses, including alcoholism, depression, and chronic medicated, unmedicated, and never-medicated first-episode schizophrenia (see text). (*Left*) Sagittal slices depicting the anatomical regions that had the maximum excessive activity are shown, and (*right*) the corresponding slices with the most deficient activity, with the corresponding most deviant very narrow band (VNB) spectral frequencies of each subtype indicated at the right side of each set of slices, are shown. Note that the most deviant excessive frequencies (Hz) of the six clusters (*left*) cover a wide range (frequency at left of each row), and were found in a diverse set of brain regions, suggesting a variety of putative upregulated neurotransmitters, while the most deficient frequencies were within a very narrow range (within the mid to high alpha band), and were found in a very consistent set of brain regions, suggesting a very small set or possibly even a single downregulated neurotransmitter. The deviation from normative values of every voxel in each slice is color-coded proportional to standard scores, with the appropriate hues corresponding to the color bar that is shown below. Note that the statistical significance of the hues of each voxel can be estimated by multiplying the *z*-score of the corresponding value from the color bar (and the palette range is indicated for each row by: *, ±1.0; **, ±2.0; ***, ±2.5) by the square root of the cluster size *N*, where: Clus 1, *N* = 53;

Clus 2, *N* = 93; Clus 3, *N* = 65; Clus 4, *N* = 24; Clus 5, *N* = 110; Clus 6, *N* = 32. Thus, all voxels colored other than gray in these slices are extremely deviant from normative values, with a minimum *P* < .001. (See eBook for color image.)

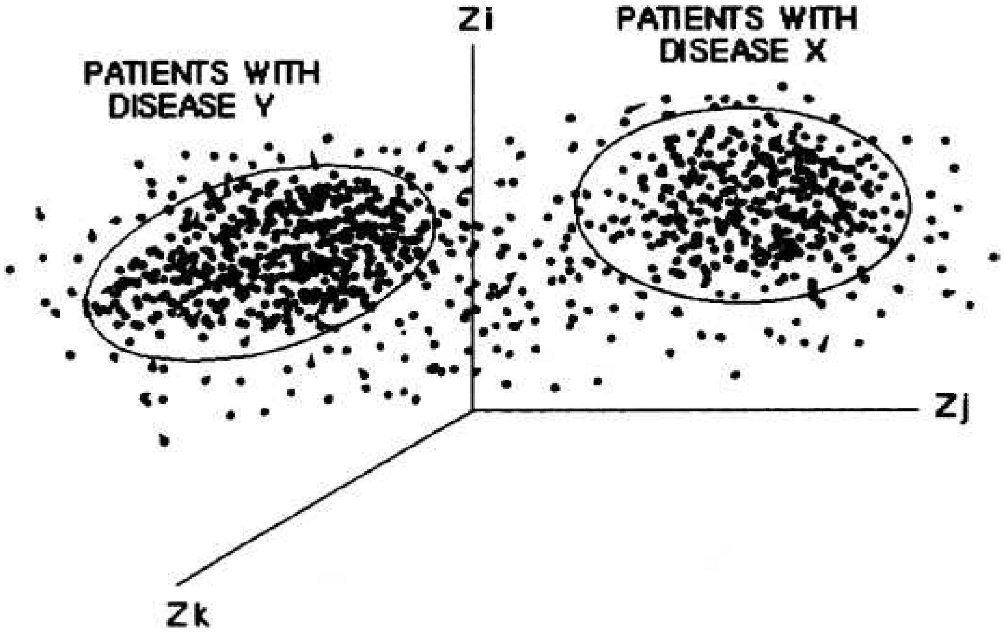

FIGURE 7.7–11. Point swarms representing the hypothetical scatter of brain state features in two different regions of a brain signal space, suggesting that discriminant classification analyses might separate patients diagnosed with Disease X from others diagnosed with Disease Y.

Statistical methods (classifier development) used to achieve separation between groups involve searching the multimodal feature space using classification methodologies and ML to identify distinctive profiles of abnormality. Several such methods exist, including genetic algorithms (GA), logistic regression, support vector machines (SVM), neural networks, and other tools, used to obtain classifier candidates that can optimally separate the two (or more) categories (disease states). For example, evolutionary algorithms (such as the GA) perform a stochastic search involving randomness from one iteration to the next and evaluates a series of candidate solutions, where each new candidate is informed by high-performing predecessors, similar to genetic evolution. The final GA solution identifies a selected set of features for which a weighted combination (when compared to a threshold derived from the receiver operator curve [ROC]) will allow probability estimates of the likelihood of belonging to one of the groups. Such classifier functions can accurately identify individuals with specific psychiatric disorders and distinguish those with one DSM diagnosis from those with a different one or from normal. Since the initial successful application of this method, numerous qEEG discriminant algorithms have been reported with sensitivity, specificity, area under the receiver operating curve (AUC), and positive and negative predictive values equal or superior to the widespread use of such well-established diagnostic imaging tools as, for example, CT for detection of stroke or TBI or MRI/DTI (diffusion tensor imaging) for concussion.

The use of qEEG features to identify an electrophysiologic biomarker of concussion has demonstrated the accuracy of such an approach. The main contributors to a concussion biomarker have been reported to be qEEG connectivity features, reflecting what is understood about the pathophysiology of concussion. Of particular importance is the demonstration of a significant correlation between this biomarker and DTI findings in the concussion population, providing evidence that this qEEG-based biomarker reflects white matter tract dysfunction.

Other studies have supported the relationship between qEEG biomarkers of neuropsychiatric disorders and advanced neuroimaging in different diagnostic groups. Such data suggests the use of qEEG as a surrogate for neuroimaging, especially at the point of care, for tracking of treatment response, and for aiding in a better understanding of the pathophysiology underlying a disorder.

Subtyping: qEEG Heterogeneity within DSM Diagnoses using qEEG Biomarkers

As is apparent from the highly variable efficacy of a given psychotropic agent in patients with the same DSM diagnosis, patients grouped together as displaying symptomatically homogeneous psychopathology may suffer from a variety of pathophysiologic dysfunctions responsive to different treatments or display different evolution of the illness. This variable responsivity suggests that individuals within the same swarm of points in a region of electrophysiologic signal space, representing first-order similarities among a group of patients with the same DSM diagnosis, might actually not be homogeneous. Within the region containing such a swarm or cloud, there might be sectors containing individuals with second-order differences in features that also contribute to their electrophysiologic profile or pattern of disorder. These differences may reflect the existence of subtypes of pathophysiology related to biomarkers that are critical for response to a given treatment, in addition to the first-order influences that produce sufficiently similar global symptoms to warrant the same DSM diagnosis, as shown schematically in Figure 7.7–12. Within the two-point swarms, the figure depicts individual members of the distinct subtypes A and B within the cloud diagnosed with disease Y and of subtypes C and D within the other cloud diagnosed with disease X. It is important to note that although referred to as “features” a feature can be a multivariate composite of more than one feature (e.g., the ratio of two features or a measure of connectivity between regions such as cordance).

In most instances, diagnosis is largely determined by clinical evaluations and DSM symptom-based categorization except for cases that present dual-diagnostic problems. Potentially, the most important and useful clinical applications of qEEG lie not just as an adjunct to diagnosis but in identifying subtypes whose members, while relatively homogeneous in terms of displaying similar symptoms and receiving like diagnoses, are statistically probable to have response-relevant differences (heterogeneous underlying qEEG profile) with respect to response to particular treatments, prognosis of evolution of illness, or prediction of treatment outcome. Investigations using methods of qEEG-based classification or cluster analyses have been useful in unmasking such heterogeneity in a number of disorders, such as (1) negative as well as positive responsiveness to or selection of stimulant therapy in ADHD; (2) response to selective serotonin reuptake inhibitors (SSRIs) in OCD (see Fig. 7.7–4, right panel, rows 1 vs. 2); (3) probability of relapse in crack-cocaine dependence; (4) pathophysiologic profiles of psychotic states or schizophrenia; (5) prediction of future cognitive decline in normal older adult; (6) response to antidepressants among patients presenting in a state of depression (see Fig. 7.7–4 left panel, row 2 vs. 3); (7) the response to nonstimulant or stimulant medication in ADHD patients; and (8) prediction of rapid or prolonged recovery in concussion. Reviews of this literature are available.

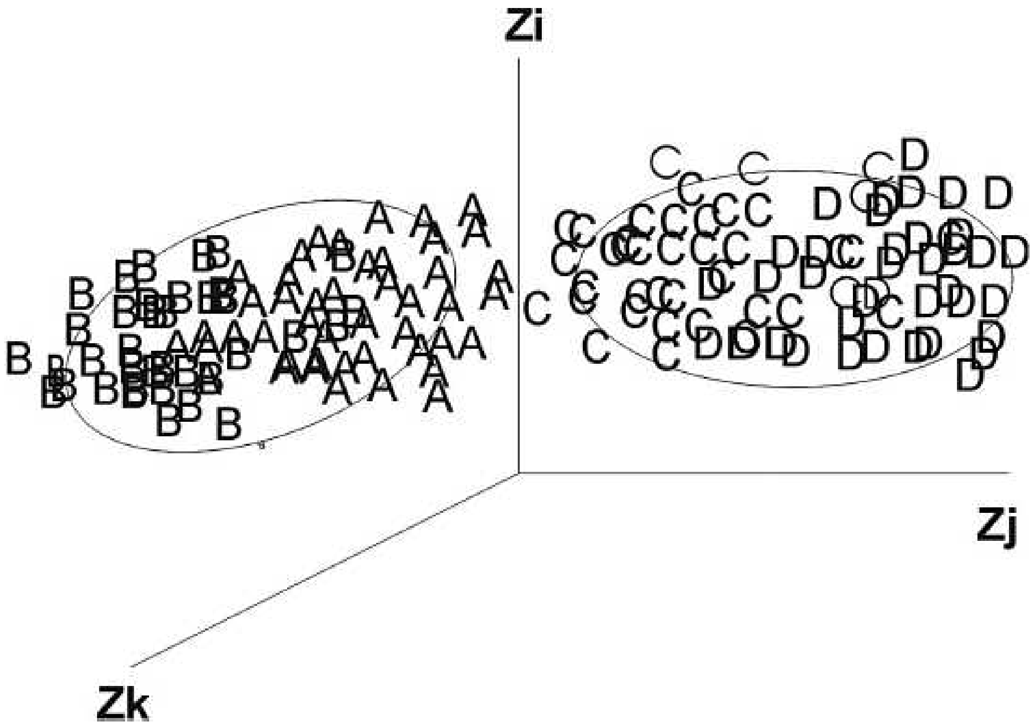

FIGURE 7.7–12. Point swarms representing the hypothetical identification of subtypes of patients in four different regions of the signal space, with different pathophysiologic profiles A and B within those diagnosed with Disease Y and with different profiles C and D within those diagnosed with Disease X.

qEEG Applications in Attention-Deficit/Hyperactivity Disorder (ADHD), Alzheimer Disease (AD), Chronic Pain, and Psychosis. The scientific literature applying qEEG methods to the study of psychiatric and neurologic patients, their diagnosis, underlying pathophysiology, and treatment response is vast and includes numerous studies in ADHD, depression, dementias, drug dependence, learning disabilities, OCD, panic disorder, schizophrenia, traumatic head injury, PTSD, chronic pain, and many other disorders. This subsection provides an overview of the literature in three areas: ADHD, dementia, and chronic pain.

Attention-Deficit/Hyperactivity Disorder

Extensive studies demonstrate the clinical utility of qEEG as an adjunct to the diagnosis, evaluation, and treatment of children, adolescents, and young adults with learning and attention problems. Using selected qEEG features (e.g., frontal theta activity or theta/beta ratio, alpha reactivity, alpha peak frequency [APF], and cordance), high accuracy, sensitivity, and specificity have been achieved in distinguishing normal controls from

ADHD/attention-deficit disorder (ADD) children, children with ADHD/ADD from those with learning disabilities, ADHD/ADD patients with a positive response to specific medication from those with a negative response. Augmenting the qEEG features with behavioral measures further enhanced the sensitivity for predicting long-term treatment response. A review of this expanding literature is available.

We will briefly summarize meta-analyses that research a large number of studies, including diagnostic capabilities, subtype identification, and treatment response in the ADHD population. One such meta-analysis of qEEG studies in ADHD (DSM-IV-TR diagnosis) reported on a total of almost greater than 1,250 patients and concluded that although many studies reported ADHD to be characterized by increased theta/beta ratios (TBR, theta power increase with a beta power decrease), this meta-analysis did not conclude that TBR is a reliable diagnostic trait of ADHD when compared to normal controls. However, results did support TBR as a prognostic value in predicting treatment outcome to stimulant medication and/or neurofeedback (NFB) in a substantial subgroup of ADHD. Additionally, more recent studies report that low frontal APF was predictive of nonresponse to methylphenidate. An additional meta-analysis reviewing NFB in ADHD reported that compared to nonactive control treatments, NF was found to have a more sustained treatment effect for at least 6 months post-treatment. Under DSM-5, ADHD has been expanded to more accurately characterize the disorder in adults as well as children and adolescents. Symptoms are still divided into categories of inattention, hyperactivity, and impulsivity. Several studies using qEEG have explored the ability to identify different patterns of abnormalities reflecting these different symptom profiles and have reported suggestive results. The existence of such electrophysiologic subtypes may be related to the prediction of different treatment responses.

The existence of electrophysiologic subtypes within the ADHD population has been further demonstrated in studies applying cluster analysis of qEEG features within a large population of ADHD patients. Such studies have shown the existence of subtypes within the population with different underlying sources for the different subtypes. While preliminary studies are suggestive of a relationship between subtype membership and treatment response, much work in larger populations remains to be done in this area.

A nonpharmacologic treatment of ADHD patients that is considerably growing is qEEG, and qEEG source, NFB. A meta-analysis including five qEEG NFB studies and a total of approximately 300 patients supports the improvement of some aspects of the ADHD symptom profile following NFB. In addition, preliminary studies have indicated the possibility of selecting NFB protocols based on individual qEEG biomarkers to optimize efficacy. More research is ongoing to support NFB as a first-line, standalone treatment modality and for the identification of the subtypes of ADHD that might most benefit from this treatment modality.

An extensive Bayesian network meta-analysis of the comparative efficacy of pharmacologic and nonpharmacologic treatments (including psychological, alternative medicine, and other treatments) of ADHD children and adolescents reported weak evidence for monotherapies being superior to placebo and that combination therapies (e.g., behavioral therapy in combination with stimulant therapy) were superior to placebo. Overall, these weak results further support that heterogeneity must be taken into account in order to adequately evaluate treatment efficacy.

Another example of the use of qEEG in the ADHD population for a better understanding of the underlying pathophysiology includes studies of alpha reactivity. This measure reflects the magnitude of the differences between alpha activity in the eyes-closed resting condition and that with eyes open with increased external stimulation. These studies suggest that ADHD patients show less alpha reactivity, supporting abnormalities in arousal mechanisms. Application of cluster analysis to the ADHD population revealed the existence of neurophysiologic subtypes and showed a relationship between cluster membership and response to treatment. qEEG source localization (VARETA) applied to individual subtypes demonstrated different underlying pathophysiology. A cluster characterized by excess alpha activity (maximum abnormality at 11 Hz, in the high alpha range) displayed primarily cortical abnormalities, maximal in right parietal cortical regions, whereas VARETA images of a cluster with theta excess (maximum abnormality at 5.4 Hz, in the theta range) revealed primarily temporal cortical and hippocampal abnormalities.

The utility of incorporating qEEG as an adjunct to the evaluation and treatment of ADHD was highlighted in a 2004 report by the American Academy of Pediatrics, which stated that “new brain wave analysis techniques like quantitative EEG will help experts more clearly document the neurologic and behavioral nature of ADHD, paving the way for better understanding and treatment.” Now, more than a decade later, a growing literature supports this thesis, and the advanced methodology implementing qEEG, ML, and subtyping addresses this need directly.

Cognitive Deterioration and Alzheimer Disease

A vast literature spanning more than three decades reports qEEG changes in the pattern of brain electrical activity associated with the severity of cognitive deterioration in older adults. Space does not permit a review of these numerous qEEG studies that consistently demonstrate the importance of the following qEEG features related to the severity and progression of dementia: Increased delta and/or theta power, decreased mean frequency of the total spectra, anteriorization of the alpha peak, decreased frequency of the dominant occipital rhythm, and changes in coherence, synchronization, and connectivity patterns. As additional advanced signal-processing methods are applied to the EEG signal, additional features have been proposed as qEEG biomarkers of disease severity in AD. These include features based on canonical correlation coefficients reflecting synchrony between multiple regions and theta current source density. A meta-analysis of portions of this literature is available.

Sensitivity to the earliest preclinical stage (i.e., the first symptomatic manifestation pre-MCI) of AD, currently described as subjective cognitive impairment (SCI), has also been demonstrated. Multiple publications have used qEEG features to achieve accurate differentiation of early AD from older adult normal controls, discrimination of dementia from depression in older adults, the distinction between early versus late-onset AD, discrimination between AD and vascular dementia, and identification of mild dementia and MCI. Further, studies demonstrate that when qEEG and ML techniques are combined with other neuroimaging methods (e.g., fMRI, MRI/DTI, SPECT), diagnostic accuracy can be increased.

The use of qEEG features observed in initial evaluations for the prediction of cognitive decline of normal older adult patients and those with MCI or early-stage mild dementia to more severe dementia has been demonstrated in multiple studies. In one such longitudinal study, the exquisite sensitivity of qEEG at the earliest stage of SCI, normal older adult subjects with only subjective complaints about memory, but no deficits on neurocognitive testing, were followed longitudinally for 7 years. On the basis of only the qEEG data from the initial qEEG evaluation, future cognitive decline was predicted with over 90% accuracy based upon subsequent clinical staging. Significant abnormalities in qEEG features were seen in the baseline evaluations of those who went on to decline and were absent in those who showed no change over time. The most salient abnormalities were seen in theta power, the mean frequency of theta and of the total spectrum, and intrahemispheric coherence across all bands. With source localization in those who go on to decline, the underlying pathophysiology identified at baseline included excessive theta activity in the hippocampus, amygdala, and temporoparietal cortex, all regions identified by other neuroimaging technology as important in dementia and related to subsequent decline to dementia. Figure 7.7–8 shows the sLORETA source localization images from the initial baseline qEEG data for the abnormal activation seen in the theta frequency band for three groups (N = 5 each group) of SCI subjects. The top row of this figure shows those who, upon long-term follow-up, were found to show no cognitive decline, the middle row shows those who are found to decline to MCI, and the bottom row shows those who convert to dementia. Such data demonstrate the high sensitivity of qEEG to the earliest signs of functional brain impairment prior to the presence of structural abnormalities. It is noteworthy that theta power has been shown to be negatively correlated with regional perfusion, especially in temporoparietal and central regions, and with PET glucose metabolism in temporoparietal and frontal regions, and is positively correlated with hippocampal atrophy seen on MRI.

Chronic Pain and Thalamocortical Dysrhythmia

Chronic pain affects over 35% of the U.S. adult population, increasing greatly in those over the age of 65. Furthermore, chronic pain is reportedly comorbid with depression in the vast majority of the patients, making chronic pain and its effective treatment a problem for both neurology and psychiatry. Contributing to the high prevalence of chronic pain and both the over- and undertreatment of the condition is the subjective standard of care for rating pain, which can lead to inappropriate and suboptimal treatment. The use of qEEG features for the objective quantification of pain has led to an increasing number of studies that have demonstrated the coregistration between functional neuroimaging studies and qEEG studies of the relationship between activation of the brain's "pain matrix" and the experience of pain intensity. Studies have emphasized that despite the high spatial resolution of neuroimaging tools, including fMRI and PET, these tools do not have the temporal resolution of qEEG, which gives them the advantage of better reflecting the dynamic nature of pain perception. Findings of qEEG source localization in pain patients support the potential to derive a quantitative measure of the severity of pain using information extracted from a multivariate descriptor of the abnormal overactivation of regions of the pain matrix. The frequency-specific (theta band) overactivation reported in the regions including the thalamus in chronic pain patients has been demonstrated in a number of studies and supports a model of thalamocortical dysrhythmia (TCD) as the mechanism of the neuropathic pain condition. This hypothesis is further supported by studies in chronic pain patients following successful central lateral nucleus thalamotomy (CLT), which showed a significant diminution in overactivation in the previously overactivated regions.

Using qEEG source localization, significant differences between those chronic pain patients and those without clinically significant depression have been shown. No significant correlation was found between the frequency-specific theta maximum abnormality in the ROIs of the Pain Matrix pain patients and the Beck depression scores in these patients. Thus, although both disorders share underlying sources in the limbic system, results support the existence of distinctive profiles of electrophysiologic abnormalities.

Figure 7.7–9 applies the methods described above to image the ROIs in chronic pain patients. A clear relationship can be seen between those regions with significant dysregulation (overactivation) and those identified using conventional, more costly, time-consuming, and not readily available neuroimaging tools. These regions include the anterior cingulate, anterior and posterior insula, parietal lobule, thalamus, S1, and dorsolateral prefrontal cortex (DLPFC). While consistent with those reported with conventional functional imaging, the use of qEEG source localization also include the mid and posterior cingulate not previously reported, suggesting that the increased temporal resolution of electrophysiologic measures allows more precise identification of the pain pathway.

Psychosis

EEG abnormalities in schizophrenic patients have been the subject of a large number of publications. Consistent descriptions of increased slow activity, especially in anterior and frontal locations, increased fast beta activity, and interhemispheric asymmetries (R > L) appear in this literature. The influence of variations of medications, chronicity of medication, and length of illness may explain some of the inconsistencies between studies. Another problem in the interpretation of these studies is the existence of electrophysiologic heterogeneity within the populations. Some studies have specifically addressed this issue, with illuminating findings that reveal subtypes with the same diagnoses but with different profiles of salient qEEG abnormalities, as well as different responses to various psychotropic medications.

The results of a qEEG subtyping study of a large population of psychotic patients are summarized here. With multivariate cluster analysis of qEEG features for a large number of psychotic patients (N = 390), including medicated, unmedicated, and never-medicated first-episode patients diagnosed with the DSM-IV or ICD-10 with schizophrenia, psychotic depression, alcohol psychosis, and other psychoses, from a multisite international study, six clusters were identified, replicating and extending prior findings in schizophrenic patients. The distribution of patients across the six subtypes found in this study was not uniform, with subtypes containing as few as 24 or as many as 110 members out of the total cohort of 390 cases. Patients bearing a diagnosis of psychotic depression or schizophrenia either on or off medication, as well as first-episode medication-naive patients, were represented in at least four of the six clusters.

All clusters showed power asymmetry in all or almost all bands and the power was greater over the right hemisphere, especially in regions of the frontal lobe. The uniform strong right hemispheric dominance of every frequency band in each cluster would suggest a general impoverishment of language. It has long been reported that left-hemispheric impairment is characteristic of schizophrenia. In particular, abnormalities of the left parahippocampal gyrus, the left medial temporal lobe, the loss of synaptic proteins from the left thalamus, etc., have been repeatedly reported in imaging studies of schizophrenic patients. Almost all clusters also displayed hypofrontality, especially in the dorsolateral and mesial prefrontal cortical regions. These findings are concordant with reports of decreased metabolism in the frontal cortex consistently noted in other functional neuroimaging studies. PET studies have shown decreased frontal but increased basal ganglia activity in schizophrenic patients, also evident in the qEEG findings, and which may reflect neocortical–striatal–

thalamocortical interactions perturbed by dopamine (DA) imbalances in psychotic patients.

This data suggest that the left-sided deficiency generalizes to psychosis, with the right hemisphere becoming dominant because of a lack of interhemispheric suppression, possibly related to the pervasive disturbance of coherence in one or another frequency band between various homologous regions, to the extent that such coherence may reflect the activation of a feedback loop between the two sides of the brain. The power dominance of the right hemisphere, together with the hypocoherence found in this study, may indicate a deficit of homeostatic feedback between homologous regions. The severe hypocoherence in both short-fiber and long-fiber tracts within each hemisphere found in every cluster in this study provides strong support for the presumption that information processing is disturbed in psychotic patients. One possible explanation of the coherence findings is that the short fiber tract hypocoherence reflects a deficit in the fast-spiking (FS) and low threshold spiking (LTS) GABAergic interneurons, modulated by DA and serotonin, which facilitate synchronization of local circuit neurons, while the long fiber tract hypocoherence reflects a deficit in the long-range interneurons which can synchronize neuronal ensembles across very long distances. There have been repeated suggestions that the personality and thought disorder observed in schizophrenics reflect the failure to integrate activity across distributed neural circuits.

Neuropsychological demonstrations of deficits in learning, memory, and executive tasks were interpreted to indicate widespread generalized fronto–limbic dysfunction. Of particular interest in the context of the authors' pervasive findings of disturbed coherence are recent neurobiologic studies of the binding process, which attribute a major role in perception and consciousness to the synchronization of EEG oscillations. Repeated reports have called attention to phase-locked oscillations in the gamma (30 to 100 Hz) frequency band. Phase-locking is a quantitative index of the temporally synchronized interactions in distributed neuronal systems. Decreased functional connectivity has also been reported in first-episode neuroleptic-naive schizophrenic patients.

VARETA source localization images of the brain regions displaying the computed intracerebral sources of the most excessive (hyperactive) and most deficient (hypoactive) activities are shown in Figure 7.7–10. These underlying sources of the qEEG clusters indicate pathophysiologic heterogeneity among patients diagnosed as psychotic, arising from two different causes of dysfunction in six basic subtypes, namely, overexcitability of one set of brain regions suggesting different underlying causes in each subtype, together with underactivation of a second set of brain regions perhaps due to the same cause in each subtype.

These clusters suggest that the optimal management of the psychotic patient will entail separately upregulating one neuroanatomical system while downregulating a different system, although it is conceivable that the distributed hypoactivity reflects inhibitory influences exerted by the hyperactive system. The regions in which homeostatic regulation is most severely disturbed (dysregulation) across all six subtypes, displaying both hyperactivity at one frequency as well as suppression of activity at a different frequency, are the amygdala, caudate, cingulate, DLPFC, hippocampus, and thalamus, suggesting that psychotic symptoms may primarily reflect a dysfunction arising from subcortical dysregulation.

Other studies have used eLORETA to evaluate the EEG Source Functional Connectivity (EEG-SFC) in schizophrenic patients. One such study compared stable medicated schizophrenia patients with healthy controls. Results demonstrated abnormalities in functional connectivity, especially in the theta frequency band where synchronization was increased (hypercoherent) in schizophrenic patients, which was increased in frontal regions with increased duration of the disease. Alpha band connectivity was seen to be decreased (hypocoherent) in frontal regions in schizophrenics and independent of the length of illness. The higher frequencies (beta1, beta2, and gamma) also showed disturbances in connectivity involving frontal regions and parietotemporal regions. The interactions found with chronicity need to be taken into consideration when interpreting such findings, but results lend support to the hypothesis of schizophrenia involving disturbances in connectivity.

qEEG-Based Depth of Anesthesia Monitor: Level of Consciousness

Instruments that use qEEG to provide dependable real-time monitors of the depth of anesthesia during surgery, measuring the level of consciousness, have demonstrated distinctive and quantitative changes from the ground state. Intraoperative studies using such instruments revealed that with loss of consciousness (LOC), there was a marked anteriorization of alpha activity into all regions of the frontal cortex, followed by a shift to a power spectrum dominated by activity in the regions of the power spectrum at the margins between delta and theta activity (2 to 4 Hz), which gradually disappeared as the patients emerged from the levels of surgical anesthesia through deep sedation to arousal. It is of particular interest that gamma coherence between prefrontal and posterior brain regions was invariantly sharply diminished precisely at LOC during anesthesia induced by any anesthetic agent studied and returned to preinduction levels just prior to the return of consciousness. While anterior–posterior coherence similarly dropped sharply at LOC for activity in the delta, theta, alpha, and beta bands, it was noteworthy that coherence for anterior–posterior neural transactions in these frequency ranges did not return to preinduction levels until as late as 10 to 15 minutes following the return of consciousness, as gauged by overt responsivity to verbal commands and speech. This suggests that gamma coherence may be of unique relevance to the maintenance of consciousness per se, which will be further elaborated in a later subsection of this section.

Application of source localization algorithms (VARETA, described above) to the EEG data collected during anesthesia revealed extensive inhibition of the frontal lobes, thalamus, basal ganglia, amygdala, and hippocampus coincident with the LOC. Return of consciousness was always preceded by reversal of the qEEG changes and disinhibition of these structures. Such findings have led to a new neurophysiologic theory of the mechanisms of action of general anesthesia.

The intraoperative studies of the invariant and reversible qEEG changes that accompanied the loss and return of consciousness are compatible with five neurophysiologic steps during the induction of surgical depth of anesthesia with any combination of agents, as follows: Step 1: Depression of the brainstem reduces the influences of the ARAS on the thalamus and cortex. Step 2: Depression of mesolimbic–DLPFC interactions leads to blockade of memory storage. Step 3: Further depression of the ARAS releases its inhibition of the nucleus reticularis of the thalamus, resulting in the closure of thalamic gates (especially in the diffuse projection system) by hyperpolarizing GABA-mediated inhibitory action of the nucleus reticularis (theta increase), thereby blocking (Step 4) thalamo–cortico–thalamo reverberations and perception (gamma decrease), so that (Step 5) parietal–frontal transactions are uncoupled (gamma coherence decreases), blocking cognition, and (Step 6) prefrontal cortex is depressed to reduce awareness (an increase of frontal delta and theta).

Since its appearance, a number of publications have confirmed various aspects of this theory, particularly with respect to the central role of the changes in coherence between anterior–posterior oscillatory activity in the gamma band. More specifically, studies of qEEG symbolic transfer entropy have shown that directional connectivity between anterior and posterior regions is inhibited by anesthesia; that there is a reorganization of hub networks from parietal to frontal regions under anesthesia; and that qEEG directional connectivity before and after LOC show decreases between the fronto–parietal and fronto–occipital regions. In summary, changes in qEEG features with loss and return of consciousness suggest an “anesthetic cascade” involving a blockade of thalamocortical reverberations and uncoupling of normal transmission between frontal and parietal/occipital regions.

THERAPEUTIC CORRECTION OF DEPARTURES FROM THE GROUND STATE

There are a number of clinical areas in which the validity of the proposition that therapeutic maneuvers that restore previously deviant qEEG features to the ground state will have a positive clinical outcome has been demonstrated. These studies suggest the possible utility of serial qEEG evaluations and the presence of electrophysiologic biomarkers as an objective adjunct to the selection of treatment, evaluation of efficacy, and optimization of dosage.

Pharmaco-EEG

Since pioneering work began in the 1960s, qEEG has been used as a tool in the development of new psychopharmaceutical agents. It was early observed, using only a few electrodes, that drugs in a particular class caused a distinctive alteration of the frequency composition of the spontaneous resting EEG. For example, anxiolytics typically cause an increase in power in the beta band, especially in EEGs recorded from electrodes over the prefrontal regions. These observations gradually became systematized so that data were collected from the full 19-channel array of the 10/20 system.

With the advent of qEEG methods, dose-response curves were calculated to correlate the amount of agent, time after administration, and quantitative changes in specific qEEG variables. It was noted that these changes followed typical time courses for different agents, indicating the potential utility of qEEG to study pharmacodynamics and bioavailability. These relationships are now sufficiently well understood for some agents that serial qEEG evaluations can be used to obtain an early indication of whether or not a specific drug and dose will be efficacious for an individual patient, and dose-response curves can be constructed using serial computations of qEEG features and the likelihood of the existence of biomarkers across successive doses.

Since under normal conditions, the qEEG is highly reproducible, in some instances, it is possible to use a simple test–retest paradigm to evaluate whether a specific drug is appropriate for an individual patient, with the two tests separated by a time interval sufficiently long to enable an effective concentration to be established in the brain. For example, in a child with ADHD/ADD who will be a good responder, within 45 minutes after a single 10-mg dose of methylphenidate, pharmacodynamic effects can be seen as a significant decrease of premedication qEEG abnormalities.

The importance of the potential contribution of qEEG to pharmacotherapy and increasing use led to the formation of a committee of thought leaders by the IPEG (International Pharmaco-EEG Society), which has published Guidelines for the Recording and Evaluation of Pharmaco-EEG in man.

Key-Lock Principle

As pharmaco-EEG knowledge accumulated, researchers discerned that certain patterns of qEEG effects were distinctive for certain classes of drugs. It gradually became apparent, at least for some conditions and some drugs, that the so-called “key-lock” principle appeared to provide a guide for the selection of medication. For example, the optimum medication for a patient whose qEEG abnormality was a deviation of the power spectrum from normative baseline with excess theta and deficit of alpha would be the pharmaceutical substance that, when administered to normal individuals, caused the appearance of the opposite power spectral deviation: Decrease of theta and increase of alpha. A body of evidence has been published that provides substantial support for this proposition.

A clinical example of this principle is demonstrated in the relationship between response to SSRIs and qEEG cluster membership shown in a study of OCD patients, all of whom were considered clinically to be candidates for SSRI treatment. Two clusters were found in this study, with differences in qEEG features that can be seen in Figure 7.7–4, where the pretreatment baselines of the two different OCD clusters are shown in the right panel rows 1 (responders) and 2 (nonresponders). One of these OCD clusters displayed an excess of theta activity (Fig. 7.7–4, right panel column 2, second row), while members of the other cluster displayed an excess of alpha power (Fig. 7.7–4, right panel column 1, first row). The effect of SSRIs on the normal EEG is to decrease alpha and increase theta activity. As can be seen in Figure 7.7–4, consistent with what would be predicted by the key-lock theory, the cluster whose baseline (pretreatment) qEEG was characterized by an excess of alpha and deficit of theta activity is the one that contained the SSRI responders (EEG normalized by the medication), and members of the cluster with an excess of theta were nonresponders.

Neurofeedback

NFB is essentially operant conditioning of brain electrical activity, first applied to the treatment of epilepsy in the early 1970s. NFB treatments postulate that: (1) continuous measurement and representation of some selected target correlate of an undesirable activity or physiologic process (autonomic measure, electromyogram [EMG]), ERP component, or composition of the qEEG power spectrum) with provision for visual or auditory feedback upon reduction of the representation or some alternative type of reinforcement to the subject whenever a decrease of the target is detected can be used to help a patient learn how to reregulate some abnormal physiologic process or aspect of brain electrical activity; and (2) that normalizing the target signal will result in a therapeutic benefit. During the last decade, a large number of practitioners have begun to use NFB to treat a wide variety of behavioral disorders and dysfunctions, most widely for ADHD but including such applications as remediation of neurologic deficits resulting from TBI or stroke. Among the several hundred papers reporting the utility of NFB are explorations of its use in addiction, ADHD, especially the suppression of undesired motor activity while remaining attentive, anxiety disorders, autism, autoimmune disorders, chronic fatigue syndrome, conduct disorder, epilepsy, learning disabilities, migraine, mood disorders, and, most recently, performance enhancement of skilled actions. In several of these areas, there have been replicated reports of statistically significant, successful reduction of the targeted symptoms. The basic method of NFB is to record a measure that reflects or is correlated with some physiologic process or condition considered undesirable, pathognomonic, or pathophysiologic, which is being continuously monitored. Some reinforcement is provided whenever the subject/patient succeeds in changing the undesirable process in a direction defined to be therapeutic, increasing or decreasing the measure. The manifestation of the undesirable condition is usually reflected in some stimulus parameter such as the intensity, pitch, or temporal pattern of an auditory stimulus or the size or brightness of a visual image, and the reinforcement is delivered by a change in the parameter, defined as a change of the undesirable process in the desired direction, such as reduction of the intensity of sound or size of a flame.

A variety of measures have been reduced successfully by NFB, including (1) ratios between qEEG measures in different bands (e.g., the “theta/alpha ratio” of the power spectrum recorded at a particular electrode position); (2) measures reflecting the autonomic nervous system, such as anxiety, galvanic skin response (GSR), high heart rate, high blood pressure, or pupillary dilatation; (3) conditions such as anxiety, attention, or obsessive behavior; (4) ERP measures considered putatively to reflect attentional processes, such as mismatch negativity (the occurrence of “different” in a sequence of paired stimuli S1 to S2 that are “same–same” or “same–different”), the amplitude of P300 in the “oddball” paradigm (in which an occasional “rare” event is interspersed in series of “common” events producing an expected late positive component to the rare event in normal cognition). A study in chronic pain demonstrated that the abnormal electrical activity at a particular frequency detected using real-time qEEG source localization within the anterior cingulate could be used for NFB to reduce intractable pain. Examples in the ADHD population are described above. A particularly novel application of NFB has been its use to enhance artistic performance, a domain in which successful intervention is a priori quite unexpected. A series of well-controlled studies sought evidence of operant control of the alpha/theta ratio, with the rationale that such control might induce a meditative state of deep relaxation. This parameter was then used to enhance performance, using criteria established by the Associated Boards of the Royal Schools of Music of England to assess variables of artistic performance, including several in the domains of instrumental competence, musicality, musical understanding, communicative ability, and overall quality. Performances were videotaped and randomized and then evaluated by experienced assessors external to the institution and blinded as to the order of performances and experimental group membership of the students. Highly significant results were obtained and successfully replicated.

An extensive review article, with a survey of evidence that validates NFB in diverse applications but particularly in ADHD and performance enhancement, has recently appeared. Although NFB was initially disparaged by many neuroscientists, neurologists, psychologists, and psychiatrists, the success and extent of this therapeutic activity are indicated by increasingly widespread utilization, and reports of carefully designed scientific studies reported in the peer-reviewed literature suggest the clinical utility of the method.

Important advances in EEG signal processing have enabled the use of real-time qEEG signal measurement, immediate data processing for feature extraction of parameters of interest, and the ability to provide feedback paradigms that use continuous measures of the EEG signal. The goal of such a method is to move the patient toward a more “normal” state, guided by their deviations from age-expected normal values. Such approaches have demonstrated the potential effectiveness of such methodology for future improved clinical utility and personalized applications of NFB.

CONSCIOUSNESS

Definition of Consciousness

Webster’s dictionary defines consciousness as “the quality or state of being aware, especially of something within one’s self.” Webster also defines awareness as “the condition of being conscious of an external object, internal state, or fact.” This tautology reflects the lack of scientific attention to this problem that persisted for much of the last century, while the question of how subjective experience arises from neural tissue was considered not a fit topic for neurobiologic research. With advances during the last decade in functional brain imaging and methods better adapted to the study of systems, neurophysiologic and psychological evidence has been forthcoming that supports a definition of consciousness as: "the subjective experience resulting from the continuous interaction of three influences: (1) incoming information about the external environment and the internal state, melded with (2) information retrieved from a dispersed memory system of stored information about previous working memory or episodic experiences that are the most currently relevant, and (3) state factors modulating both our perceptions of and our reactions to the outer world, by affecting arousal levels, emotional states, and moods."

"Relevant" means those experiences for which the environmental and physiologic state-generated inputs are most evocative because of inherent salience and situational correspondence or their multisensorial similarities. "Modulated" means the biasing of apperception and memory selection due to more global, direct, or indirect influences of humoral factors to alter the excitability of components of both the responsive and the reactive systems.

INFORMATION IS SYNCHRONOUS DEVIATIONS FROM GROUND STATE

If the billions of neurons whose activity is sensed by an EEG electrode were discharging completely at random, then there would be no net voltage detectable by the electrode. Voltage excursions in the resting EEG or ERPs that cause the qEEG power spectrum to deviate from the ground state represent temporal fluctuations in underlying regions of the synchronized activity of a significantly great number of neurons relative to the proportion that would be expected to discharge together solely by chance. Analogously, the images of sensory, perceptual, or cognitive processing detected by fMRI represent the spatially distributed decrease in oxyhemoglobin caused by metabolic requirements of massively synchronized ensembles of brain cells, relative to reference background activity. All such ensembles are intimately interconnected and in constant bidirectional transactions with numerous other ensembles of neurons at varying distances. The homeostatically regulated ground state of the resting EEG power spectrum of every brain region, as well as the remarkable stability of transactions reflected in the coherence and symmetry among these regions within and between the hemispheres, indicates that the spontaneous synchronization of nonrandom firing within and among regional populations of neurons is dynamically restricted and constrained within well-defined limits and regulated by positive and negative feedback processes. The constancy of these quantifiable variables of brain electrical activity over sustained time periods, in spite of the known fluctuations in excitability of individual neurons, indicates that this stability reflects a basic property of the large-scale organization of the central nervous system. Consistency with the concept of the DMN is noted.

Such predictable background brain activity contains no information because the information is that which cannot be predicted. Significantly nonrandom or synchronous brain electrical activity beyond these constrained limits constitutes a deviation from the homeostatically regulated ground state that defines the information content of that perceptual moment and causes the EEG voltage to deviate from the regulated range of random fluctuations. Spatially dispersed nonrandom synchrony is the key signature of significant informational activity within the brain. Information, retrieval of memories, and the generation of the perceptual content of moments of consciousness are encoded as temporal patterns of synchronized nonrandom activity in very large ensembles of neurons distributed spatially in the exogenous and endogenous systems causing dispersed neuronal ensembles to deviate from the ground state. One might speculate that brief excursions around the constrained baseline of the ground state reflect the sporadic thoughts that fleet through the mind of a person resting quietly, which rapidly converge to the ground state unless they are long sustained.

Discontinuity of Consciousness

Subjectively, consciousness appears to be continuous and unitary, that is, seamless. However, psychophysiological studies indicate that perceptual processes within the brain are discontinuous, parsing consciousness into successive “perceptual frames,” or moments of subjective experience. Under controlled experimental conditions, if the interval between two stimuli becomes as short as 80 to 100 milliseconds, then the pair merge into a single event. Although the EEG at every electrode position on the head appears to be an apparently continuous time series of voltages, the topography of the variance of the local deviations from the average voltage over the entire scalp, or global field power (GFP), is also discontinuous. A limited number of topographies actually wax and wane at rather regular intervals that have been called “microstates” or “atoms of thought," found to have an average duration of about 82 ± 2 milliseconds within a normally functioning healthy population of 500 subjects ranging in age from 6 to 90. Similar discontinuities have been found in magnetoencephalographic (MEG) research. Such evidence suggests that the apparent continuity of subjective time is an illusion produced by neurophysiologic processes parsing information into successive chunks about 80 to 100 milliseconds in duration.

On average, four spatial topographies account for 94% of the variance of the scalp EEG, mapping the field in four basic modes: Activation of the right anterior hemisphere, left anterior hemisphere, frontal cortex, and motor cortex. These may, respectively, represent the encoding of spatial information in the environment, verbal encoding of that information, executive interpretation and evaluation of the verbal–spatial representation of the environment in view of relevant memories, especially of the recent past, and the organization of adaptive language and motoric responses. The transitions among modes tend to follow a particular sequence in normal subjects but are found to be different in patients with some psychiatric disorders.

Parallel Multiplexed Information Processing Channels

Although evidence shows that perceptual frames last about 80 to 100 milliseconds, other experiments have established that temporal discriminations can be made at substantially shorter intervals, on the order of tens of milliseconds or less. Thus, the neural receptor systems mediating each sensory modality may be organized into multiple parallel channels, containing perceptual frames offset from one another by a fixed time, like commonly used multiplexing of information. Using averaging techniques time-locked to the presentation of a specific sensory stimulus is equivalent to demultiplexing, enabling the electrical activity reflecting the processing of information in only one of these parallel channels to be extracted as an ERP. It is important to stress that dispersed neuroanatomical structures containing the other parallel channels in the afferent pathways are not only processing that information but are simultaneously engaged in many other neural transactions, continuously active during the time required for the averaging process. As the time-locked activity of one channel converges to a stable ERP wave shape, considered as "*signal,*" the ongoing activity in all of the other channels converges to zero because it is in a random phase relative to the time of stimulus presentation and is considered as "*noise.*" The signal-to-noise ratio in the ERP waveshape extracted by the averaging process is improved proportionally to the square root of the number of samples that have been averaged. If subjective experiential continuity is mediated by consecutive inputs from these hypothesized multiplexed channels, then *consciousness must reflect a global statistical steady state maintained within a spatially extensive brain system that is independent of any individual neurons.*

Construction of Consciousness

The brain is organized to assign an affective and experiential label on every moment of input from the environment that causes a significant nonrandom discharge. When such a discharge is provoked by external or exteroceptive stimuli, it activates a network of neuronal ensembles linking the sensory receptors to subcortical structures in the brainstem and the thalamus, causing volleys of oscillatory activity to be propagated to dispersed regions of the primary sensory cortex and to cortical association areas, providing a fractionated representation of the *present.* These volleys propagate in parallel to structures such as the amygdala, entorhinal cortex, hippocampus, and septum comprising the limbic system, merging with and modulating the relevant activated readout from the *past,* as well as to subcortical structures such as the basal ganglia and hypothalamus reflecting *internal state,* that together mediate emotional valence and motivation as well as motoric organization. A spatially extensive set of nonrandom electrical cortico–limbic–subcorticocortical oscillations links these structures, *binding* them into a dynamic functional network. That which is linked becomes phase-locked and coherent, producing an instant of subjective experience that merges the present with selected aspects of the past: the "*remembered present.*" These coherent discharges define all of the information in the brain at any moment, which must subsume the content of consciousness. Therefore, the content of consciousness logically must arise from this spatially extensive nonrandomness.

The discrete parsing of information into sequential segments in each modality, integrated across modalities during the microstates, is experienced as a series of apparently continuous perceptual frames. The remainder of this chapter attempts to describe how activity in exogenous and endogenous systems is combined to construct the remembered present, first taking advantage of knowledge about the processing of information within only one of the hypothesized channels, a snapshot artificially visualized by the ERP averaging strategy, as described in Figure 7.7–13. The authors consider the EEG to be an envelope integrating simultaneous time-shifted voltage sequences produced by multiple processes similar to this example, occurring in numerous parallel networks offset by the multiplexing time delay as the environment is continuously sampled by the brain.

Neurophysiologic, psychophysiological, and fMRI research, for which reviews are available elsewhere, provides evidence supporting the concept that "mental chronometry" is reflected in the successive peaks of the cortical ERPs during the processing of information. The first positive component (P1) is associated with the arrival of information reporting the sensation of the stimuli, the negative-positive complex N1P2 is associated with attending to the input, the second positive cortical component (P2) is related to the perception of the stimuli, and a later positive component (P3) reflects the cognitive interpretation or "meaning" of the events.

Modulated Exogenous–Endogenous Interaction

As the described construction of consciousness proceeds, each perceptual frame or moment of subjective experience is constructed from interactions between three systems, analogous to a *mental molecule* rather than an atom of thought.

1. An "*exogenous system*" disperses spatiotemporal patterns of activity representing multimodal encoding of the environment to *basal dendrites* of pyramidal neurons throughout the neocortex, modulated by influences of internal state. Discrete attributes are distributed to many different brain regions to be analyzed before they are recombined. Information from different sensory modalities requires disparate times to be dispersed in pathways of different lengths and propagation velocities, so the sustained persistence of the perceptual frame may be essential for information from disparate modalities to be synthesized into one simultaneous multimodal percept.
2. In parallel, an "*endogenous system*" disperses spatiotemporal patterns of input to the *apical dendrites* of the pyramidal neurons representing the readout of memories about the most relevant and salient past experiences. Evidence suggests that an "auto-associative" readout process, based upon multimodal similarities between previous patterns

of activity and the exogenous report of the present, retrieves a facsimile of stored experiences from extensive networks in regions of the limbic system and the basal ganglia, as well as throughout the association regions of the cortex.

3. A “*state, modulation system,*” mediated by interneurons that reflect the state of sympathetic–parasympathetic balance of the autonomic nervous system and endocrine and adrenal activity, act upon large populations of pyramidal neurons at levels of basal or apical dendrites to weigh the relative contributions of the exogenous and endogenous systems, “reality” and “the past,” to the content of consciousness. These interneurons, by nonsynaptic modulation of membrane thresholds as well as synaptic input to pyramidal neurons, have the capability to differentially shift or bias the global thresholds of huge populations of neurons. They can desensitize or hypersensitize the exogenous system to certain kinds of afferent input and increase or diminish the salience of past experiences released from the endogenous systems.

FIGURE 7.7–13. Sequential steps of “mental chronometry” constructing a perceptual frame are postulated to occur simultaneously in numerous parallel processing channels, combining information from the exogenous and endogenous system into a seamless subjective moment of the “remembered present.” Incoming information from sensory receptors is propagated via the thalamocortical relay (TCR) nuclei to basal dendrites of feature-extracting pyramidal neurons dispersed throughout the neocortex in layer 5, producing the first positive (P50) event-related potential (ERP) component (at time *t*, about 50 ms) and simultaneously enters the reticular formation, registering the first elements of sensation. Activated cortical regions instruct the nucleus reticularis to inhibit selected regions of thalamic neurons to enhance the relevant signal-to-noise ratio, producing negative deflections (N150) (at time *t* + 1, about 130 ms) related to attention, while the ascending reticular arousal system (ARAS) sends information to the intralaminar nuclei and the raphe nuclei, hypothalamus, and septum. From the intralaminar nuclei, activity propagates to the apical dendrites of pyramidal cells of the posterior and associative cortical regions, producing the second positive (P200) ERP deflection (at time *t* + 2, about 210 ms) related to perception, and is sent as well from the dorsomedial thalamus to the basal dendrites of the prefrontal cortex and into the entorhinal cortex. Such incoming information from the exogenous system then circulates through the hippocampus and related structures of the limbic system, activating the most relevant past experiences by auto-associative mechanisms. Retrieved memories and their associated valence and context are projected via the entorhinal cortex and the anterior cingulate to the prefrontal cortex and thence to the posterior cortex, producing P300, the third positive ERP component (at time *t* + 3, about 300 ms) related

to cognition and subjective interpretation of the “meaning” of the percept. A late negative component, N400, reflects semantic encoding. Dispersed elements of sensations are linked into perceptions and interpreted cognitively in the context of past experience by binding mechanisms, reflected by the appearance of widespread gamma oscillations among dispersed anatomical regions.

Neuron–Interneuron Interactions

Each interneuron may contact as many as tens of thousands of pyramidal neurons, synchronizing theta and gamma oscillatory neuronal networks engaged in cognitive and emotional processing. Fast spiking (FS) basket cells surround the basal regions, which receive the major inputs from the exogenous system, while LTS basket cells can modulate apical dendrites, which receive the major inputs from the endogenous system and potentially affect mood and recollections relevant to depressive and schizophrenic pathophysiology. Long-range interneurons are “interregional” and facilitate rapid synchronization. Thus, interneuron influences continuously modulate the input and output to pyramidal cells serving as coincidence detectors between elements of the past and the present, as schematized in Figure 7.7–14.

In particular, the release by the locus ceruleus of serotonin and DA can differentially inhibit the release of GABA from FS interneurons to modulate attentional and arousing effects and salience of inputs from the exogenous system onto the basal dendrites of the pyramidal neurons while inhibiting the input of the LTS interneurons to the apical dendrites. Conversely, the release of an adrenal cortical hormone (ACH) and norepinephrine by the nucleus basalis can modulate the excitability of the LTS interneurons and selectively block GABA, disinhibiting thalamic neurons from the inhibitory influences of the nucleus reticularis.

LTS interneurons can display self-induced slow, long-lasting inhibition (SSI) mediated by endocannabinoids, decreasing their inhibitory influences. The resulting heightened excitability of the apical dendrites increases the influences of the endogenous system. Intense activation of the LTS interneurons would lead to SSI, giving an avalanche of positive feedback to the pyramidal neurons due to disinhibition. Imbalance in a specific neurotransmitter might activate a subset of GABAergic interneurons, synchronizing remote ensembles of pyramidal neurons into closely phase-locked rhythmic activity. Such synchronization could enhance or diminish the impact of the environment and experiences upon the exogenous and endogenous systems and their interactions, changing the flavor of the “remembered present.”

Coincidence Detection Constructs Fractionated Elements of Perception

Incoming sensory activity is dispersed by the TCR nuclei to the basal dendrites of pyramidal neurons in layers four and five of receiving regions throughout the sensory cortex, specialized to detect specific features of the multimodal focus of attention, as shown by red and blue arrows in the upper panel of Figure 7.7–15. Outputs from an “endogenous system” activated by this information and reflecting recent events, combined with signals reflecting internal state, are sent via the ARAS and the diffuse projection system to apical dendrites of the pyramidal neurons in the association and prefrontal cortices, where they are combined with input from primary receiving areas. This convergence, shown by mauve arrows in the middle panel of Figure 7.7–15, has been shown to be critical for the perception of a sensation to be accomplished.

Binding, Resonance, and Consciousness

The “binding problem” is the question of how attributes of multiple sensory modalities comprising these dispersed fragments of perception are recombined into a holistic perceptual moment of subjective experience, augmented by the associated affect, emotion, and motivational valence. Convergence of similar temporal patterns, arriving via the exogenous inputs upon the basal synapses and via the endogenous system upon the apical synapses of selected neurons in the layers of pyramidal cells dispersed throughout the cortex, results in a coherent corticothalamic discharge of synchronous volleys from this population, with a back-propagated oscillation in the gamma frequency range (~40 Hz). This oscillation causes these regions to depart from the ground state and establishes dispersed fragments of *local negative entropy,* that is, *improbably* synchronized spatiotemporal activity patterns that represent fractionated elements of perception.

FIGURE 7.7–15. Schema of the stages of construction of conscious awareness and evaluation of percepts as derived from sensations are depicted. (*Top*) Sensations are produced by unimodal information (*red and*

blue) propagating from specific thalamocortical relay nuclei to dispersed sensory-specific cortical receiving areas, with distribution (*mauve*) into nonspecific thalamic and limbic system components of the endogenous system via the reticular formation. (*Middle*) Perception requires the coincidence of exogenous inputs (*red and blue*) to basal dendrites with inputs from the endogenous system (*mauve*) to apical dendrites of pyramidal cells in association and frontal cortical regions. (*Bottom*) Cognition is mediated by the binding together of activated dispersed cortical regions with activated specific and nonspecific thalamic nuclei in a coherent, phase-locked, reverberating gamma oscillation (*green*). (See eBook for color image.)

When enormous numbers of pyramidal neurons dispersed throughout numerous brain regions thus oscillate, reverberation links these regions together by phase-locked transcortical gamma oscillations. At the same time, neuronal ensembles comprising the networks of the endogenous system release memories retrieved by the autoassociative processes, which are reflected by gamma oscillations phase-locked to theta waves propagated to the prefrontal and association areas of the cortex. Cortical pyramidal cells in these regions appear to serve as coincidence detectors that coregister the present with the past. These spatially dispersed oscillations in the same high-frequency range, engaging the cortex, thalamus, subcortex, and limbic system, are physically brought into phase by electronic coupling, perhaps mediated by gap junctions and glial cells, and are thereby bound together. This system of temporally patterned, spatially dispersed but phase-locked, high-frequency oscillations of electrical energy begins to resonate, represented by the green arrows in Figure 7.7–13. Coherent gamma oscillations between prefrontal and parietooccipital areas of the cortex are essential for consciousness, as shown by their invariant reversible disappearance and reappearance with loss and return of consciousness in qEEG studies of anesthesia.

This resonance among spatially dispersed neuronal masses results in a shift of the brain from the homeostatically regulated ground state, which creates an extremely improbable informational field of global negative entropy. Phase-locking and resonance bind the exogenous and endogenous systems together into a continuously updating, globally coherent, anatomically dispersed yet cohesive functional network, whose operation is independent of any dedicated neuron or a specific set of neurons; the posterior regions of the brain (the sensory-specific, association, and motor cortices), dominated by inputs reporting the present state from the exogenous, autonomic, and musculoskeletal systems, are coupled together in global resonance with the anterior regions (the precentral and frontal cortices), dominated by the input of readout from the most relevant endogenous emotional, motivational, and motoric state and memory systems distributed among subcortical structures, including the basal ganglia, thalamus, hypothalamus, and limbic system.

Consciousness is postulated to be a physical property of this organized informational field of global negative entropy dynamically constructed in this spatially extensive resonating system, not a localized process mediated by discrete neuronal transactions. While neuronal activity generates this property, consciousness is not directly a neuronal process but rather a consequence emerging from mass action of enormous numbers of neurons, just as a nuclear explosion is not a property of the fission of an atom. Disturbances in the regulation of these complex transactions among masses of neural tissue are very relevant to the emergence of psychiatric disorders. Such disturbances might variously arise from dysfunction in the exogenous encoding mechanisms, the endogenous auto-associative retrieval mechanisms, or biasing of thresholds due to phasic or tonic fluctuations of the modulatory interneuron meshwork and can be envisaged potentially to generate psychopathological symptomatology. Malfunction of either or all of the exogenous, endogenous, and modulatory systems may distort the subjective experience to produce misperceptions and maladaptive behavior. Not only may each analytical apparatus be defective, but the binding process itself may be askew. The symptoms of many psychiatric disorders may reflect the disorganization of integrative processes dependent upon these binding mechanisms.

CONCLUSIONS

This section has provided an overview of the methods of qEEG and a summary of evidence of its sensitivity and specificity for detecting pathophysiologic conditions in a variety of psychiatric disorders and for identifying treatment-responsive and outcome-related subtypes within disorders. Identification of these distinctive profiles of disorders has been aided by the use of ML-driven classification methods. It has also called attention to the powerful brain imaging capabilities using qEEG source localization, allowing imaging of the mathematically most probable underlying sources of the scalp-recorded data superimposed on a normal MRI template, greatly expanding the potential to contribute to the understanding of the pathophysiology of psychiatric disorders and the clinical utility of qEEG in psychiatric populations. Growing evidence of the correlation between qEEG and other neuroimaging tools underscores the power of qEEG as a more readily available, nonradiation-emitting, cost-effective surrogate of advanced functional neuroimaging, which can be used at the point of care. Space did not permit a review of the contribution of sleep EEG. However, reviews of this literature exist.

This chapter has also presented a theoretical framework that the authors believe is pertinent to an understanding of how the measurements available with qEEG can be used to gain insights into the underlying neurophysiologic factors that may be contributory to the maladaptive behavior and emotional distress suffered by patients with a psychiatric/neuropsychiatric disorder. These symptoms can be thought of as reflecting perturbations of one or another aspect of the system that the authors have proposed to mediate the subjective content of conscious experience. The authors believe that systematic interactions between the symptoms experienced by the patient, the observations of the psychiatrist, and the careful evaluation and interpretation of functional assessments, obtained using readily available qEEG and source localization imaging technology evaluated relative to normative data, can focus attention upon disturbances of equilibrium in the brain. This, in turn, can lead to evidence-guided hypotheses about appropriate most optimal modes of treatment and targets for new and more personalized treatments, with iterated quantitative neurobiologic as well as psychiatric assessment of the appropriateness and efficacy of the treatment.

7.8 Psychiatric Rating Scales

Samuel Justin Sinclair, Ph.D., Mark A. Blais, Psy.D., and Deborah Blacker, M.D., Sc.D.

The term *psychiatric rating scales* encompasses a variety of questionnaires, interviews, checklists, outcome assessments, and other instruments that are available to inform psychiatric practice, research, and administration. Although new instruments and alternative versions of older instruments (especially shorter, self-report, or telephone versions) are developed regularly to improve quality and efficiency, to update diagnostic criteria, and to measure emerging constructs, they tend to be adopted slowly, as evidence of their usefulness accumulates. Older measures slowly fall out of favor as they become outdated and are supplanted by newer measures. Psychiatrists must keep up with major developments in rating scales for several reasons. Most critically, many such scales are useful in psychiatric practice for monitoring patients over time or for providing information that is more comprehensive than what is generally obtained in a routine clinical interview. In addition, healthcare administrators and payors are increasingly requiring standardized assessments to demonstrate the efficacy of psychiatric services or to assess quality of care. Last, but equally important, rating scales are used in research that informs the practice of psychiatry, so familiarity with them provides a deeper understanding of the results of that research and the degree to which it applies to psychiatric practice.

POTENTIAL BENEFITS AND LIMITATIONS OF RATING SCALES IN PSYCHIATRY

In its latest release of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), the American Psychiatric Association (APA) advocates for the use of psychometric tools in clinical practice as a means of improving quality of care at multiple levels. These new “emerging measures” are presented in Section III of the DSM-5, and include tools for both adults and children that are designed to assess an array of clinical domains (e.g., depression, anxiety, mania, etc.), which may then call attention to potential areas of difficulty and guide the clinical evaluation process. Likewise, more in-depth psychometric tools are also included to provide for more comprehensive assessments of specific domains (e.g., depression, mania, substance use), which then can be used to track symptom profiles over time. APA discusses a number of advantages of using these types of assessment tools, including the improvement of clinical precision and decision-making at the point of initial evaluation, a standardized method/metric for evaluating treatment efficacy over time, and finally as a framework for tracking patient-reported outcomes (PROs) more globally.

The key role of rating scales in psychiatry and elsewhere is to standardize the information collected across time and observers. This standardization ensures a consistent and comprehensive evaluation that may aid treatment planning by establishing a diagnosis, assuring a thorough review of symptoms, identifying comorbid conditions, and characterizing other factors affecting treatment response. In addition, the use of a rating scale can establish a baseline for following the progression of an illness over time or in response to specific interventions. This is particularly useful when more than one clinician is involved—for instance, in a hospital, group practice or research setting.

In addition to standardization, most rating scales provide users with empirical information about the measure's performance characteristics. This allows the clinician to know to what extent a given scale produces reproducible results (reliability) and how it compares to more established ways of measuring the same construct (validity).

Rating scales also offer some practical advantages. First, they offer carefully worded, pretested methods for obtaining information that can save valuable physician time—self-administered rating scales can be completed in the waiting room, or a nurse or technician can administer an interview before a session with the physician. In addition, rating scales may make it easier to obtain information about sensitive areas, such as cognitive decline or sexual side effects, in which direct questioning may be experienced as intrusive.

It is important to realize, however, that rating scales are not a panacea. They can provide erroneous measurements due to difficulties in administration, measurement error (or statistical imprecision), or limitations in the underlying construct. In this respect, they are no different than clinical assessments, but may appear to provide more definitive information and thus a spurious sense of security. At the practical level, they take time that might be better devoted to other clinical activities. The critical decision when deciding to use a formal assessment tool in clinical practice is whether, on balance, it contributes useful information in an efficient manner. This decision depends on the specific clinical setting and goal, the practical attributes of the scale, and its psychometric properties.

TYPES OF SCALES AND WHAT THEY MEASURE

Psychometric tools are used in psychiatric research and practice to achieve a variety of goals. They also cover a wide range of areas and use a broad array of procedures and formats.

Measurement Goals

Most psychiatric rating scales fall into one or more of the following categories: Making a diagnosis (e.g., the Structured Clinical Interview for the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5] [SCID] or the Diagnostic Interview Schedule for Children [DISC]); measuring severity and tracking change in specific symptoms (e.g., the Hamilton Anxiety Rating Scale [HAM-A] or the Mini-Mental State Examination [MMSE]), in general functioning (e.g., the Short-Form 36 [SF-36]), or in overall outcome (e.g., the Behavior and Symptom Identification Scale [BASIS-24]); and screening for conditions that may or may not be present (e.g., the CAGE).

Constructs Assessed

Psychiatric practitioners and investigators assess a broad range of areas, referred to as *constructs,* to underscore the fact that they are not simple, direct observations of nature. These include diagnoses, signs and symptoms, severity, functional impairment, quality of life, and many others. Some of these constructs are fairly complex and are divided into two or more domains (e.g., positive and negative symptoms in schizophrenia, or mood and neurovegetative symptoms in major depressive disorder). Many scales yield separate scores, or *subscales,* for each domain. In cases in which these domains are seen as substantially independent, they may be referred to as *dimensions* (e.g., the DSM-5 hybrid dimensional-categorical model proposed in Section III).

Categorical versus Continuous Classification. Some constructs are viewed as *categorical* or classifying, whereas others are seen as *continuous*. Categorical constructs describe the presence or absence of a given attribute (e.g., whether someone meets criteria for depression or not), or the category best suited to a given individual among a finite set of options (e.g., assigning a diagnosis). Continuous measures provide a quantitative assessment along a continuum of intensity, frequency, or severity (e.g., the magnitude or degree of someone's level of depression). In addition to symptom severity and functional status, multidimensional personality traits, cognitive status, social support, and many other attributes are generally measured continuously.

The distinction between categorical and continuous measures is by no means absolute. *Ordinal* classification, which uses a finite, ordered set of categories (e.g., unaffected, mild, moderate, or severe) stands between the two. In addition, a cutoff is frequently used with a continuous or ordinal scale to indicate a threshold for membership in a corresponding category. For instance, individuals with MMSE scores below 24 may be considered to have a dementia, or those with Hamilton Rating Scale for Depression (HAM-D) scores above 8 may be considered to have an episode of major depression.

Measurement Procedures

Rating scales differ in measurement methods. Issues to be considered include format, raters, and sources of information.

Format. Rating scales are available in a variety of formats. Some are simply checklists or guides to observation that help the clinician achieve a standardized rating. Others are self-administered questionnaires or tests. Still others are formal interviews that may be *fully structured* (i.e., specifying the exact wording of questions to be asked) or *semi-structured* (i.e., providing only some specific wording, along with suggestions for additional questions or probes). Whether fully structured or not, instruments may be written such that all questions are always included, or they may have formal skip-out sections to limit administration time.

Individual items also vary in format. Most commonly, scales use questions with yes–no or multiple-choice response options. Often, answers will be graded on a *Likert* scale, an ordinal scale with three to seven points that measures severity, intensity, frequency, or other attributes. Likert scales are most often partially or fully *anchored,* assigning a meaning to each numeric level. The same anchors can apply to all of the items, or the instrument may provide specific anchors for each. Occasionally, questionnaires include open-ended questions, especially at the beginning, which may be used to help establish rapport. In semi-structured or unstructured interviews, this information also serves to guide the rest of the interview and to aid in forming a clinical impression about the patient.

Raters. Some instruments are designed to be administered by doctoral-level clinicians only, whereas others may be administered by psychiatric nurses or social workers with more limited clinical experience. Still other instruments are designed primarily for use by lay raters with little or no experience with psychopathology. In general, more training is required to administer less structured scales. In addition, some scales require extensive training, even for experienced clinicians, to master the appropriate procedures and achieve a good result. Virtually all scales perform better when raters are familiar with their format and specific content.

Source of Information. Instruments also vary in the source of information used to make the ratings. Information may be obtained solely from the patient, who generally knows the most about their condition. In some instruments, some or all of the information may be obtained from a knowledgeable informant. When the construct involves limited insight (e.g., cognitive disorders or mania) or significant social undesirability (e.g., antisocial personality or substance abuse), other informants may be preferable. Informants may also be helpful when the subject has limited ability to recall or report symptoms (e.g., delirium, dementia, or any disorder in young children). Some rating scales also allow or require information to be included from medical records or from patient observation.

ASSESSMENT OF RATING SCALES

In clinical research, rating scales are mandatory to ensure interpretable and potentially generalizable results, and are selected based on coverage of the relevant constructs, expense (based on the nature of the raters, purchase price if any, and necessary training), length and administration time, comprehensibility to the intended audience, and quality of the ratings provided. In clinical practice, one considers these factors and, also, whether a scale would provide more or better information than what would be obtained in ordinary clinical practice or would contribute to the efficiency of obtaining that information. In either case, the assessment of quality is based on *psychometric,* or mind-measuring, properties.

Psychometric Properties

The two principal psychometric properties of a measure are *reliability* and *validity.* Although these words are used almost interchangeably in everyday speech, they are distinct in the context of evaluating rating scales. To be useful, scales should be *reliable,* or consistent and repeatable even if performed by different raters at different times or under different conditions; and they should be *valid,* or accurate in representing the true state of nature.

Relationship Between Reliability and Validity. Establishing a measure's reliability is generally considered primary, as it is difficult to reach valid judgments without first achieving consistency. However, problems with reliability can be overcome to an extent by combining information from several assessments. Unfortunately, improved reliability does not guarantee improved validity, and some efforts to improve reliability may actually limit validity. For example, a personality disorder instrument might focus on overt behaviors rather than inner thoughts and feelings to achieve higher reliability, but at the cost of losing some of the most valid information about personality. Even with clinically trained raters, it is particularly difficult to achieve reliability on items requiring subjective clinical judgment (e.g., feelings evoked in the examiner). Nonetheless, when used by experienced diagnosticians, such items may contribute substantially to valid diagnoses.

Reliability. *Reliability* refers to the consistency or repeatability of ratings and is largely empirical. In the categorical context, it refers to whether there is agreement on the classification of each individual. In the continuous context, it refers to whether there is agreement on the assignment of a given score. It can also be seen as precision (i.e., whether a measure yields a “ballpark” estimate or a finely graded score). An instrument is more likely to be reliable if the instructions and questions are clearly and simply worded, and the format is easy to understand and score. There are three standard ways to assess reliability: *Internal consistency, interrater,* and *test–retest.*

INTERNAL CONSISTENCY. Internal consistency assesses agreement among the individual items in a measure. This provides information about reliability, because each item is viewed as a single measurement of the underlying construct. Thus, the coherence of the items suggests that each is measuring the same thing. Internal consistency is measured most often with *coefficient alpha* (also known as *Cronbach coefficient alpha*), which ranges between 0 and 1—values of 0.70 are typically recommended when evaluating or making decisions about groups of people, whereas more stringent values (usually exceeding 0.85 or 0.90) are suggested when evaluating individuals. However, it should be noted that the internal consistency of a *measure* depends on the internal consistency of the *construct* that the measure purports to assess and will be higher for unidimensional constructs than for those with two or more relatively independent domains. For multidimensional constructs, it is generally preferable to calculate coefficient alpha on individual subscales.

INTERRATER AND TEST–RETEST RELIABILITY. Interrater (also called *interjudge* or *joint*) reliability is a measure of agreement between two or more observers evaluating the same subjects using the same information. Estimates may vary with assessment conditions—for instance, estimates of interrater reliability based on videotaped interviews tend to be higher than those based on interviews conducted by one of the raters. Interrater reliability tends to be higher than *test–retest reliability,* a measure of agreement between evaluations at two points in time in which there may be differences in the information obtained (e.g., associated with differences in interviewer skill, interviewer mood, room conditions, or subject’s attitude). In addition, test–retest evaluations measure reliability only to the extent that the subject’s true condition remains stable in the time interval, which is problematic for many conditions but virtually impossible for rapidly fluctuating conditions like state anxiety. However, the test–retest situation more closely reflects the clinical problems associated with serial evaluations by multiple clinicians, so to the extent that concerns about interval change can be eliminated, it is generally a more useful indicator of reliability in practice.

Interrater reliability and test–retest reliability of continuous constructs are measured with the intraclass correlation coefficient (ICC), whereas those of categorical constructs are measured with the kappa coefficient (κ). A weighted version of κ is available to give greater penalties for large disagreements than for small ones (e.g., between schizophrenia and psychotic depression, as compared to schizophrenia and schizoaffective disorder), or for ordinal measures. Both κ and the ICC are measures of agreement corrected for the agreement expected by chance alone, and both range from 0 to 1. As a rule of thumb, a κ or ICC above 0.8 is considered excellent, those in the 0.7 to 0.8 range are considered good, and those in the 0.6 to 0.7 range are considered fair. However, the degree of reliability required varies with the clinical purpose: Extremely reliable ratings are required to measure small changes in critical values (e.g., to detect small effects in a clinical trial or to decide when to stop a potentially toxic therapy), whereas more modest reliability may be satisfactory for other purposes (e.g., to detect large effects in a clinical trial or to estimate population means or rates).

ISSUES IN INTERPRETING RELIABILITY DATA. When interpreting reliability data, it is important to bear in mind that reliability estimates published in the literature may not generalize to other settings. Factors to consider are the nature of the sample, the training and experience of the raters, and the test conditions. Issues regarding the sample are especially critical. In particular, reliability tends to be higher in samples with high variability in which it is easier to make discriminations among individuals. Thus, for continuous measures, reliability tends to be higher when the sample includes individuals with a wide range of scores; and for categorical measures, reliability tends to be higher when the prevalence of the attribute being measured approaches 50%. Reliability estimates also depend on the fraction of difficult cases (e.g., individuals near a diagnostic threshold or those resistant to being interviewed), as large numbers of these tend to diminish observed reliability.

Validity. *Validity* refers to conformity with truth, or a gold standard that can stand for truth. In the categorical context, it refers to whether an instrument can make correct classifications. In the continuous context, it refers to accuracy, or whether the score assigned can be said to represent the true state of nature. Although reliability is an empirical question, validity is partly theoretical—for many constructs measured in psychiatry, there is no underlying absolute truth. Even so, some measures yield more useful and meaningful data than others do. Validity assessment is generally divided into face and content validity, criterion validity, and construct validity.

FACE AND CONTENT VALIDITY. *Face validity* refers to whether the items appear to assess the construct in question. Although a rating scale may purport to measure a construct of interest, a review of the items may reveal that it embodies a very different conceptualization of the construct. For instance, an insight scale may define *insight* in either psychoanalytic or neurologic terms. However, items with a transparent relationship to the construct may be a disadvantage when measuring socially undesirable traits, such as substance abuse or malingering. *Content validity* is similar to face validity, but differs in that it describes whether the measure provides good and balanced coverage of the construct, and is less focused on whether the items give the appearance of validity. Content validity is often assessed with formal procedures such as expert consensus or factor analysis.

CRITERION VALIDITY. *Criterion validity* (sometimes called *predictive* or *concurrent validity*) refers to whether or not the measure agrees with a gold standard or criterion of accuracy. Suitable gold standards include the long form of an established instrument for a new, shorter version; a clinician-rated measure for a self-report form; and blood or urine tests for measures of drug use. For diagnostic interviews, the generally accepted gold standard is the *L*ongitudinal, *E*xpert, *A*ll *D*ata (LEAD) standard, which incorporates expert clinical evaluation, longitudinal observations, medical records, family history, and any other sources of information.

When continuous measures are compared to a gold standard, a correlation coefficient is the statistic most often reported. For categorical variables, such as diagnoses (or continuous measures with a cutoff), various types of diagnostic efficiency statistics are employed depending on the goal of the study—most commonly *sensitivity* and *specificity*. *Sensitivity* refers to the test's ability to identify true cases, or its *true-*

positive rate. Specificity is the test's accuracy in identifying noncases, or one minus the *false-positive rate.* In general, the more sensitive a test, the less specific it is. If the threshold for diagnosis, for example, is lowered, then more cases will be detected but at the expense of some false positives; if the threshold is raised to decrease the false positives, then true cases will inevitably be missed. The optimal threshold depends on the consequences of false positives and false negatives. Calculation of predictive value positive and negative, which report, respectively, the proportion of positive and negative assessments that are correct *in a given population,* may help to answer this question. Predictive value positive, for instance, can be low even with excellent specificity in a low prevalence population, for instance, when measuring psychotic disorders in the general population. Where sensitivity is low, predictive value negative may be reduced, but less so if prevalence is also low.

CONSTRUCT VALIDITY. When an adequate gold standard is not available—a frequent state of affairs in psychiatry—or when additional validity data are desired, construct validity must be assessed. To accomplish this, one can compare the measure to *external validators,* attributes that bear a well-characterized relationship to the construct under study but are not measured directly by the instrument. External validators used to validate psychiatric diagnostic criteria and the diagnostic instruments that aim to operationalize them include course of illness, family history, and treatment response. For example, when compared to schizophrenia measures, mania measures are expected to identify more individuals with a remitting course, a family history of major mood disorders, and a good response to lithium.

Two special cases of assessing validity using external validators have particular relevance for clinical psychiatry. One is *discriminant validity,* which examines a measure's ability to discriminate between populations that are expected to differ on the construct of interest. For example, does a sociopathy measure correctly separate individuals in jails from those living in the community? Although such discriminations are important in clinical practice, it is important to remember that the true test of a measure is its ability to discriminate at the margins. A study of discriminant validity is more clearly relevant if it includes the types of cases encountered in clinical practice (e.g., psychotic depression versus schizoaffective disorder) rather than more easily discriminated populations (e.g., psychotic depression versus normal). Another special case is *sensitivity to change:* The fact that a measure shows expected changes (e.g., an improvement with an efficacious treatment or a decrement with a progressive disease) can be a strong validator.

When validity is assessed in areas in which there are few established measures and a gold standard or criterion of accuracy cannot be established, the assessment of the validity of the measure is limited by the validity of the construct itself. Nonetheless, by triangulation between a better definition of the construct, better ways to measure it, and better exploration of how it operates in clinical practice and research, the field moves to greater validity over time. Cronbach and Meehl (1955) referred to this process as defining the *nomological net* of constructs to be measured and ways in which they are thought to be interrelated, which then provides a framework for evaluating and establishing construct validity.

SELECTION OF PSYCHIATRIC RATING SCALES

In this section, a group of rating scales used in psychiatric practice and research is presented. The scales are grouped by topic, beginning with general issues, including diagnosis, functioning, symptom severity, and side effects, and then proceeding to specific diagnostic groups, organized according to the sections of the DSM-5. Selections were made based on coverage of major areas and common use in clinical research or current (or potential) use in clinical practice; instruments specifically recommended in DSM-5 were included whenever possible. For each area, there is a brief discussion of measurement issues followed by a description of each instrument, its psychometric properties, and its potential uses. In addition, whenever possible, a brief, clinically useful instrument is provided in each area. References for each measure, organized by topic, are listed in Table 7.8–1. These references include more detailed information about each measure and its psychometric properties and may also provide either the measure itself or instructions regarding how to obtain a copy. Access to instruments via the internet is increasing rapidly, but internet addresses evolve still more rapidly, so they are not included here. Instead, a quick search using Google or a similar search engine is recommended to locate a website that may offer the instrument for purchase or download, an up-to-date list of references, and other information.

Functional Status, Impairment, and General Symptom Severity

This broad area cuts across a variety of diagnoses and is thus useful for grading patients by functional status or overall severity without reference to specific symptomatology. Most of the instruments presented here have a strong mental health focus and often include items on psychiatric symptomatology.

The World Health Organization Disability Assessment Schedule. The World Health Organization Disability Assessment Schedule (WHODAS 2.0) was published in 2010 by the World Health Organization (WHO), and is a 36-item, self-administered measure of disability across six distinct domains including: understanding and communicating, getting around, self-care, getting along with people, life activities (i.e., household, work, and/or school activities), and participation in society. An informant (proxy) version of the tool is also available. Each of the 36 items is rated along a five-point Likert scale (1. None, 2. Mild, 3. Moderate, 4. Severe, 5. Extreme), and then items are summed within the six domains. Scores are linearly transformed to a 0 to 100 metric, where 0 represents no disability and 100 represents maximum disability. Based on DSM-5 field trials of the WHODAS 2.0 in adult populations, the APA has recommended that *average* scores for each domain be used as a means of helping clinicians to think about disability status in terms of the five anchor (scaling) points noted above (no disability, mild, moderate, severe, and extreme disability). This scoring method was found to be reliable, clinically useful, and with promising validity. It also provides clinicians with an alternative method for quantifying level of functioning (or degree of impairment) related to psychiatric symptoms given that DSM-IV's Global Assessment of Functioning (GAF) scale was not retained in DSM-5.

Behavior and Symptom Identification Scale. The Behavior and Symptom Identification Scale (BASIS-32) was developed in the early 1990s to provide a broad but brief overview of psychiatric symptoms and functional status from the patient's point of view for use in assessing the outcome of psychiatric treatment. A revised version, the BASIS-24 (Table 7.8–2), aimed at making the instrument shorter and more broadly applicable across demographic and diagnostic groups and in a wider variety of treatment settings, was released in 2004. The instrument assesses a wide range of areas, including family and work relationships; ability to complete regular tasks at home, work, or school; and symptoms of anxiety, depression, psychosis, and substance abuse. Each item is rated on a five-point scale focused on the degree of difficulty the individual has had in a given area during the preceding week. The BASIS-24 can be completed as a paper-and-pencil test (requiring 5 to 20 minutes), or the questions can be read aloud with the patient selecting the best answer from a laminated card (requiring 15 to 20 minutes). The BASIS-24 is scored by computer and generates an overall score and five subscales: relation to self and others, daily living and role functioning, depression and anxiety, impulsive and addictive behavior, and psychosis. Good reliability and validity have been demonstrated. Its simple administration, brevity, and broad coverage make it well suited to its original task, and it is frequently used at baseline, during treatment, and after treatment to monitor progress. It is capable of providing valid ratings across a wide range of psychiatric impairment but is not generally suitable for individuals with substantial cognitive impairment. It is also not suitable for children under 14 years of age.

Table 7.8–2.
BASIS-24 (Behavior and Symptom Identification Scale)

Instructions to Staff: Please fill in the following information completely.

Client ID: _ _ _ _ _ _ _

HCO ID: _ _ _ _ _ _ _

Admission/Intake Date: _ _/_ _/_ _

Time Point:
$_1$☐ Admission/Intake
$_2$☐ Mid-treatment
$_3$☐ Discharge termination
$_4$☐ Post-treatment follow-up

Level of Care:
$_1$☐ Inpatient
$_2$☐ Outpatient
$_3$☐ Partial/day hospital
$_4$☐ Residential

Program Type or Unit: _ _

Instructions to Respondents:

This survey asks about how you are feeling and doing in different areas of life. Please check the box to the left of your answer that best describes yourself during the *PAST WEEK.* Please answer every question. If you are unsure about how to answer, please give the best answer you can.

EXAMPLE: ***During the past week,*** **how much difficulty did you have sleeping?**
$_0$☐ No difficulty
$_1$☐ A little difficulty
$_2$☐ Moderate difficulty
$_3$☐ Quite a bit of difficulty
$_4$☐ Extreme difficulty

During the PAST WEEK, how much difficulty did you have…

1. Managing your day-to-day life?
$_0$☐ No difficulty
$_1$☐ A little difficulty
$_2$☐ Moderate difficulty
$_3$☐ Quite a bit of difficulty
$_4$☐ Extreme difficulty

2. Coping with problems in your life?
$_0$☐ No difficulty
$_1$☐ A little difficulty
$_2$☐ Moderate difficulty
$_3$☐ Quite a bit of difficulty
$_4$☐ Extreme difficulty

3. Concentrating?
$_0$☐ No difficulty
$_1$☐ A little difficulty
$_2$☐ Moderate difficulty
$_3$☐ Quite a bit of difficulty
$_4$☐ Extreme difficulty

During the PAST WEEK, how much of the time did you…

4. Get along with people in your family?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

5. Get along with people outside your family?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

6. Get along well in social situations?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

During the PAST WEEK, how much of the time did you…

7. Feel close to another person?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

8. Feel like you had someone to turn to if you needed help?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

9. Feel confident in yourself?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

During the PAST WEEK, how much of the time did you…

10. Feel sad or depressed?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

11. Think about ending your life?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

12. Feel nervous?
$_0$☐ None of the time
$_1$☐ A little of the time
$_2$☐ Half of the time
$_3$☐ Most of the time
$_4$☐ All of the time

During the PAST WEEK, how often did you…

13. Have thoughts racing through your head?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

14. Think you had special powers?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

15. Hear voices or see things?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

16. Think people were watching you?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

17. Think people were against you?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

During the PAST WEEK, how often did you…

18. Have mood swings?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

19. Feel short-tempered?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

20. Think about hurting yourself?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

During the PAST WEEK, how often…

21. Did you have an urge to drink alcohol or take street drugs?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

22. Did anyone talk to you about your drinking or drug use?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

23. Did you try to hide your drinking or drug use?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

24. Did you have problems from your drinking or drug use?

$_0$☐ Never
$_1$☐ Rarely
$_2$☐ Sometimes
$_3$☐ Often
$_4$☐ Always

ABOUT YOU

25. How old are you?—

26. What is your sex? $_1$☐ Male
$_2$☐ Female

27. Are you … $_1$☐ Hispanic or Latino
$_2$☐ NOT Hispanic or Latino

28. What is your racial background?

$_1$☐ American Indian or Alaskan native
$_2$☐ Asian
$_3$☐ Black or African-American
$_4$☐ White/Caucasian
$_5$☐ Native Hawaiian or other Pacific Islander
$_6$☐ Multiracial or other (specify)

29. How much school have you completed?

$_1$☐ 8th grade or less
$_2$☐ Some high school
$_3$☐ High school graduate/GED
$_4$☐ Some college
$_5$☐ 4-year college graduate or higher

30. Are you now …

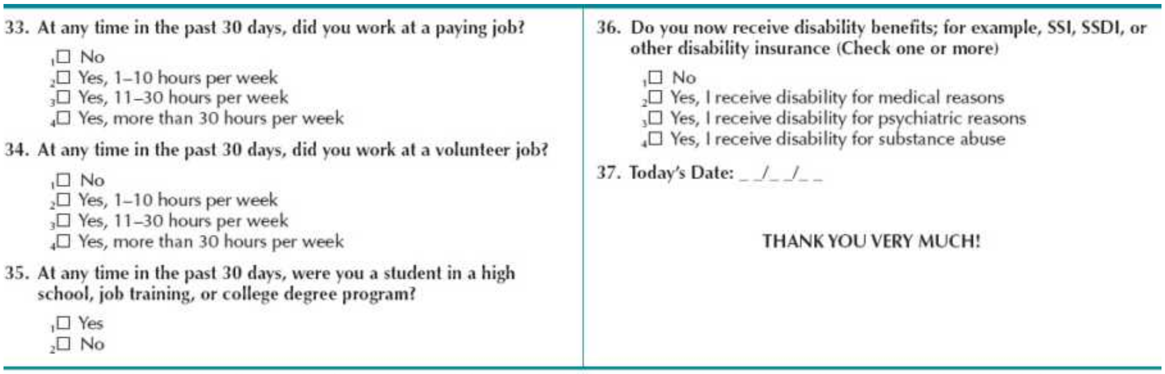
$_1$☐ Married
$_2$☐ Separated
$_3$☐ Divorced
$_4$☐ Widowed
$_5$☐ Never married

31. Outside of your treatment providers, what is your main source of social support?

$_1$☐ Wife, husband, or partner
$_2$☐ Other family (parents, children, relatives)
$_3$☐ Friends/roommates
$_4$☐ Community/church
$_5$☐ Other
$_6$☐ No one

32. Where did you sleep in the past 30 days?

$_1$☐ Apartment or house
$_2$☐ Halfway house/group home/board and care home/residential center/supervised housing
$_3$☐ School or dormitory
$_4$☐ Hospital or detox center
$_5$☐ Nursing home/assisted living
$_6$☐ Shelter/street
$_7$☐ Jail/prison
$_8$☐ Other (fill in)________________



33. At any time in the past 30 days, did you work at a paying job?

$_1$☐ No
$_2$☐ Yes, 1–10 hours per week
$_3$☐ Yes, 11–30 hours per week
$_4$☐ Yes, more than 30 hours per week

34. At any time in the past 30 days, did you work at a volunteer job?

$_1$☐ No
$_2$☐ Yes, 1–10 hours per week
$_3$☐ Yes, 11–30 hours per week
$_4$☐ Yes, more than 30 hours per week

35. At any time in the past 30 days, were you a student in a high school, job training, or college degree program?

$_1$☐ Yes
$_2$☐ No

36. Do you now receive disability benefits; for example, SSI, SSDI, or other disability insurance (Check one or more)

$_1$☐ No
$_2$☐ Yes, I receive disability for medical reasons
$_3$☐ Yes, I receive disability for psychiatric reasons
$_4$☐ Yes, I receive disability for substance abuse

37. Today's Date: _ _/_ _/_ _

THANK YOU VERY MUCH!

Short-Form 36. The SF-36 was developed in 1993 as a general measure of health status from the patient's point of view that would be independent of specific diseases and equally applicable to medical and psychiatric patients and to the general population. It is part of a broader family of instruments designed for this purpose. The SF-36 consists of 36 items, a mixture of yes–no questions and short Likert scales. It is focused on the individual's functional status as it relates to physical problems, pain, and emotional difficulties over the last 4 weeks. An acute version, focused on the past week, is also available, as are 8- and 12-item versions; the 4-week, 36-item version is the most widely used. The items are used to rate eight separate subscales: physical function, physical role function, pain, general health, vitality, social function, emotional role function, and mental health. Computer programs are available for administration and scoring. It is designed as a self-report instrument but can easily be read by an interviewer in person or over the phone. The instrument can be completed in 10 to 15 minutes. It has been subjected to extensive psychometric testing in clinical and general population samples, with extensive norms available. There is demonstrated high internal consistency for the eight subscales and good test–retest reliability over a 2-week period. Validity has been demonstrated by correlation with other functional scales and with various severity-of-illness and burden-of-care scales. The SF-36 is in wide use around the world, especially in health services research, and the instrument has special utility for comparing health outcomes across disparate diagnostic groups. It can also be used in clinical and health administration practice to track outcomes for individual patients or health systems and offers the benefit of patient-centered assessment of treatment and its impact.

Side Effects

The instruments described below are used to detect and quantify side effects from medications. One is a general interview that is applicable to all medications. The remaining two (the Abnormal Involuntary Movement Scale [AIMS] and the Simpson-Angus Rating Scale for Extrapyramidal Side Effects) are focused on the motor symptoms commonly observed with antipsychotics and, for this reason, include a brief focused physical examination, as well as questions posed to the patient.

Systematic Assessment of Treatment-Emergent Events. The Systematic Assessment of Treatment-Emergent Events (SAFTEE) is a systematic tool developed in 1986 to assess side effects in clinical trials. It has two versions, a general inquiry form (SAFTEE-GI) and a much more detailed specific inquiry form (SAFTEE-SI) that incorporates a formal review of symptoms. The SAFTEE-GI is rated based on three open-ended questions regarding new symptoms experienced in the past week: (1) Have you had any physical or health problems during the past week? (2) Have you noticed any changes in your physical appearance during the past week? (3) Have you cut down on the things you usually do because of not feeling physically well during the past week? To avoid bias on the part of the examiner or patient, the questions are focused on the novelty of the symptoms rather than on any relationship to the drug. The SAFTEE form provides specified terms (listed by organ system) for reporting the answers to the three questions and suggests specific ways to follow up on any positive answers regarding (1) the duration, temporal pattern, severity, and associated functional impairment for each; (2) any contributory factors other than the drug (e.g., other medication changes or intercurrent illness) and any hypothesized relationship of the drug to the event (e.g., dose response or noted in other subjects); and (3) any observed changes in behavior and appearance (e.g., shortness of breath or rash). The SAFTEE-GI takes 5 to 10 minutes to administer if there are few symptoms but could potentially take much longer. The SAFTEE-GI has fair to good reliability in use (somewhat better for the presence of symptoms than for detailed ratings such as severity). The SAFTEE-GI has good validity based on a comparison with similar measures and on its ability to detect expected side effects. The SAFTEE-GI is more sensitive to side effects than is typical clinical practice, and the SAFTEE-SI is more sensitive still. Although the SAFTEE-SI is only suitable for use in research settings, the

SAFTEE-GI could be used in clinical practice when a new drug is administered as a complement to specific questions about expected side effects of a particular drug.

Abnormal Involuntary Movement Scale. The AIMS (Table 7.8–3) is a clinical examination and rating scale developed in the 1970s to measure dyskinetic symptoms in patients taking antipsychotic drugs. The AIMS has 12 items, each of which is rated on an item-specific five-point severity scale ranging from 0 to 4. Total scores are not generally reported. Instead, changes in global severity and individual areas can be monitored over time. Ten items cover the movements themselves, divided in sections rating global severity and those related to specific body regions; two items concern dental factors that can complicate the diagnosis of dyskinesia. In the presence of extended neuroleptic exposure and the absence of other conditions causing dyskinesia, mild dyskinetic movements in two areas or moderate movements in one area suggest a diagnosis of tardive dyskinesia. The AIMS was developed for clinician raters, but lay raters can be trained to use it. It can be completed in less than 10 minutes. Excellent reliability has been demonstrated, especially for experienced raters, and the instrument appears valid. The AIMS is considered standard clinical practice for patients receiving long-term neuroleptic drugs in many clinical settings and is essential in clinical practice and research, both for monitoring patients for the development of tardive dyskinesia and for tracking changes in tardive dyskinesia over time.

Table 7.8–3.
Abnormal Involuntary Movement Scale (AIMS) Examination Procedure

Patient identification: ________________ Date: ________________

Rated by: ________________

Either before or after completing the examination procedure, observe the patient unobtrusively at rest (e.g., in waiting room).

The chair to be used in this examination should be a hard, firm one without arms.

After observing the patient, they may be rated on a scale of 0 (none), 1 (minimal), 2 (mild), 3 (moderate), and 4 (severe) according to the severity of symptoms.

Ask the patient whether there is anything in their mouth (i.e., gum, candy, etc.) and if there is to remove it.

Ask patient about the current condition of their teeth. Ask patient if they wear dentures. Do teeth or dentures bother patient now?

Ask patient whether they notice any movement in mouth, face, hands, or feet. If yes, ask to describe and to what extent they currently bother patient or interfere with their activities.

0 1 2 3 4	Have patient sit in chair with hands on knees, legs slightly apart, and feet flat on floor. (Look at entire body for movements while in this position.)
0 1 2 3 4	Ask patient to sit with hands hanging unsupported. If male, between legs; if female and wearing a dress, hanging over knees. (Observe hands and other body areas.)
0 1 2 3 4	Ask patient to open mouth. (Observe tongue at rest within mouth.) Do this twice.
0 1 2 3 4	Ask patient to protrude tongue. (Observe abnormalities of tongue movement.) Do this twice.
0 1 2 3 4	Ask the patient to tap thumb, with each finger, as rapidly as possible for 10–15 seconds; separately with right hand, then with left hand. (Observe facial and leg movements.)
0 1 2 3 4	Flex and extend patient's left and right arms. (One at a time.)
0 1 2 3 4	Ask patient to stand up. (Observe in profile. Observe all body areas again, hips included.)
0 1 2 3 4	Ask patient to extend both arms outstretched in front with palms down. (Observe trunk, legs, and mouth.)[a]
0 1 2 3 4	Have patient walk a few paces, turn and walk back to chair. (Observe hands and gait.) Do this twice.[a]

---

[a] Activated movements.

Simpson-Angus Rating Scale for Extrapyramidal Side Effects. The Simpson-Angus Rating Scale for Extrapyramidal Side Effects was developed to monitor the effects of antipsychotic drugs. It has ten items, each of which is rated on an item-specific five-point severity scale ranging from 0 to 4. Scores are reported as the mean on all ten items, with 0.3 considered the upper limits of normal. It is strongly focused on parkinsonian symptoms, particularly rigidity, but includes one akathisia item. It is designed for clinician use but can be administered by trained lay raters and takes approximately 10 minutes to administer. Good reliability has been reported, and validity is supported by the correlation of scores with antipsychotic drug dose. The scale is useful in a wide variety of clinical and research settings to monitor parkinsonian side effects and the impact of interventions to treat these effects.

Psychiatric Diagnosis and Screening

Instruments assessing psychiatric diagnosis are central to psychiatric research and may be useful in clinical practice as well. However, they tend to be rather long, especially when administered to individuals reporting many symptoms, potentially requiring many follow-up questions. When such instruments are evaluated, it is important to be sure that they implement current diagnostic criteria and cover the diagnostic areas of interest. For instance, few cover personality disorders (with the exception in some cases of antisocial personality), and not all cover disorders that typically onset in childhood.

Structured Clinical Interview for DSM. The SCID was initially developed in the early 1990s to provide a standardized DSM-III-R Axis I diagnosis based on an efficient but thorough clinical evaluation and is sometimes referred to as the SCID-I to distinguish it from the SCID-II, a similar measure for personality disorders. It was subsequently updated for the DSM-IV in 1994 and DSM-5 in 2015. The semi-structured diagnostic interview begins with a section on demographic information and clinical background. Then there are eight diagnostic modules focused on different diagnostic groups: mood, psychotic, substance abuse, anxiety, obsessive-compulsive and related disorders, feeding and eating disorders, externalizing disorders, and trauma and stressor-related disorders. Both required and optional probes are provided, and skip outs are suggested where no further questioning is warranted. All available information, including that from hospital records, informants, and patient observation, should be used to rate the SCID. The SCID is designed to be administered by experienced clinicians and is generally not recommended for use by lay interviewers. In addition, formal training in the SCID is required, and training books and videos are available to facilitate this. For individuals without symptoms, the interview takes approximately 1 hour to complete but may take up to 3 hours for individuals with extensive symptomatology. Although the primary focus is research with psychiatric patients, a nonpatient version (with no reference to a chief complaint) and a more clinical version (without as much detailed subtyping) are also available. Reliability data on the SCID suggest that it performs better on more severe disorders (e.g., bipolar disorder) or alcohol withdrawal than on milder ones (e.g., persistent depressive disorder [dysthymia]). Validity data are limited, as the SCID is more often used as the gold standard to evaluate other instruments. It is considered the standard interview to verify diagnosis in clinical trials and is extensively used in other forms of psychiatric research. Although its length precludes its use in routine clinical practice, the SCID can sometimes be useful to assure a systematic evaluation in psychiatric patients—for instance, on admission to an inpatient unit or at intake into an outpatient clinic. It is also used in forensic practice to assure a formal and reproducible examination.

The MINI International Neuropsychiatric Interview (MINI). The MINI International Neuropsychiatric Interview (MINI) is a structured diagnostic interview that was originally developed in 1990 by researchers in the United States and Europe for purposes of assessing DSM-III-R and ICD-10 psychiatric conditions. It has since been updated several times to evaluate for DSM-IV and DSM-5, and has been translated and validated in over 70 languages. It assesses the 17 most common psychiatric disorders in mental health—selected based on prevalence rates of 0.5% or greater in the general population. Similar to the SCID, the MINI uses a branching tree logic interview structure in order to quickly determine whether symptom criteria are met. In addition to the standard MINI, there are multiple other versions available for use in research settings, including for general screening, psychotic disorders studies, attention-deficit hyperactivity studies, eating disorders studies, tobacco use disorder studies, suicidality disorders, and tracking. There is also a MINI KID version that assesses the 30 most common psychiatric disorders in pediatric mental health—along with briefer screening versions organized by domain. The MINI is a proprietary instrument requiring a licensing agreement to use, and training is recommended. Psychometric studies of the MINI have indicated they yield similar reliability and validity coefficients as the SCID, but can be administered in a much shorter period of time.

Patient Health Questionnaire. The Patient Health Questionnaire (PHQ) is a self-administered screening instrument designed primarily for primary care. It was developed in 1999 based on the earlier Primary Care Evaluation of Mental Disorders (PRIME-MD). It focuses on more common disorders likely to be seen in primary care settings: major depressive disorder, panic disorder, somatoform disorder, binge-eating disorder, alcohol abuse, and subthreshold depression and anxiety. It has 54 questions and takes 5 to 10 minutes to complete and thus can easily be completed in the waiting room. The primary care provider then reviews the positive responses and derives diagnoses in 1 to 5 minutes from a review of the patient's answers and an accompanying checklist. Training in the use of the instrument or careful review of the instruction manual is recommended. Reliability appears to be fair to good, better for more severe diagnoses. Validity judged against psychiatrist evaluations is quite good. The PHQ appears to be useful for primary care settings but lacks appropriate coverage for the range of disorders seen in psychiatric settings. Shorter versions, the PHQ-9 and PHQ-2, have been developed explicitly for primary care screening for depression (see below).

The American Psychiatric Association's DSM-5 Cross-Cutting Symptom Measures. With the release of the DSM-5, the APA has proposed several screening measures that can be used at the point of initial evaluation in order to guide the process of diagnosis and treatment, or to track a range of symptoms that cut across diagnostic boundaries. These instruments are referred to as the DSM-5 Self-Rated Level 1 Cross-Cutting Symptom Measures, and self-administered forms are available for adults and children (aged 11 to 17). There is also a parent/guardian rated form for children (aged 6 to 17). The adult form contains 23 items tapping 13 domains (Depression, Anger, Mania, Anxiety, Somatic Symptoms, Suicidal Ideation, Psychosis, Sleep Problems, Memory, Repetitive Thoughts and Behaviors, Dissociation, Personality Functioning, and Substance Use); whereas the Child form contains 25 items tapping 12 domains (Somatic Symptoms, Sleep Problems, Inattention, Depression, Anger, Irritability, Mania, Anxiety, Psychosis, Repetitive Thoughts and Behaviors, Substance Use, and Suicidal Ideation). All items are rated along the same five-point Likert scale (None, Slight, Mild, Moderate, Severe), and the highest scores are recorded for each domain. These measures were developed using a combination of items drawn from existing validated measures (e.g., the two depression items were taken from the PHQ 2-item screening measure for depression) and novel items developed by the DSM-5 working group (e.g., the two personality functioning items and one dissociation item). To date, these tools do not include a specific norm-based scoring procedure. Rather, the current convention is to recommend further evaluation (e.g., via more detailed Level 2 scales [available in DSM-5-TR]) for any score of “2” (mild) or greater on any scale (or 1 or greater for suicidal ideation, substance use, and psychosis).

Broadband Measures of Psychological Functioning

The field of psychometrics has evolved considerably over the last 50 years, and has given rise to a number of broadband measures of psychological functioning that have been shown to be psychometrically robust and strong predictors of important clinical outcomes. Among the most well-known are the Minnesota Multiphasic Personality Inventory (MMPI), the Personality Assessment Inventory (PAI), and the more recent Spectra: Indices of Psychopathology. These types of measures allow clinicians to evaluate a wide array of important clinical domains (which may be particularly useful at the point of initial evaluation or in cases where diagnosis may be complex and/or ambiguous) while also assessing other important factors such as test validity (i.e., inconsistent and/or idiosyncratic responding), response style (e.g., whether someone may be presenting in an overly positive or negative manner), interpersonal style, and suicide and violence risk. The strengths of these measures include their comprehensive scope and more systematic evaluation of an array of clinically relevant domains. At the same time, such instruments may also be time-consuming and overly taxing for the patient, and thus careful consideration should be given a priori as to whether and under what conditions this type of assessment would prove most useful. For example, these assessments may be inappropriate in acute settings, where patients may lack the cognitive and emotional resources to complete such a long instrument, and effort may be better spent in administering more targeted (and briefer) assessments instead.

Over the last decade, there has also emerged an accumulating body of research revealing the presence of multiple higher-order domains of psychopathology, which may explain the covariance (i.e., comorbidity) often observed across many types of psychiatric disorders. These higher-order dimensions have commonly been referred to as: Internalizing (unipolar depression, generalized anxiety, social phobia, panic disorder, posttraumatic stress); Externalizing (alcohol abuse, drug abuse, impulsivity, aggression, and adult antisocial behavior); and Reality-Impairing pathology (e.g., psychotic experiences, paranoid ideation, grandiose ideation, and manic activation). Using this *hierarchical-dimensional model* of psychopathology as a framework, there have also recently emerged a number of broadband measures which evaluate these constructs at multiple levels—including the Spectra: Indices of Psychopathology.

The Minnesota Multiphasic Personality Inventory. The standard MMPI-2 is a 567-item, self-administered instrument that assesses a broad range of psychopathology, while also providing indicators of test validity, response style, and interpersonal functioning. It takes roughly 45 to 60 minutes to complete, and uses a standard computer scoring program that produces a profile of scores which clinicians are then able to interpret relative to established population norms. MMPI items are rated along the same True/False scale, which map onto 10 clinical scales (Hypochondriasis, Depression, Hysteria, Psychopathic Deviate, Masculinity/Femininity, Paranoia, Psychasthenia, Schizophrenia, Hypomania, Social Introversion). Likewise, the MMPI also includes a number of validity scales evaluating for response consistency, idiosyncratic responding, and negative and positive response styles. A wide range of other scales have also been developed *post-hoc,* and are included in the current scoring programs available from the test publisher. The original MMPI was initially developed in the early 1940s and restandardized in 1989 (MMPI-2), and there now exist several different versions of the tool, including one for adolescents (MMPI-A) and a somewhat shorter, reformatted version (MMPI-2-RF) based on more modern psychometric methods. The MMPI is among the most widely researched broadband measures of psychological functioning, and its validity and reliability have been well-established across a wide array of clinical and nonclinical settings.

Most recently, the MMPI-3 was published in 2020. A revision of the MMPI-2-RF, the MMPI-3 was developed specifically for purposes of updating item content and coverage, and providing new normative benchmarks for interpretation—with a strong emphasis on establishing sound psychometric properties. At 335 items, the instrument takes about 25 to 30 minutes to complete (per the test publisher), and can be administered electronically or with paper and pencil. Normative data is available both for a nationally representative (census-matched) sample of English-speaking adults (age 18+) living in the United States (*N* = 1,620), as well as a sample of 550 U.S. Spanish speakers. The MMPI-3 has also been translated into Spanish, French, and Canadian versions.

The Personality Assessment Inventory. The PAI was published in 1991, and is a 344-item, multi-scale, self-report assessment tool that assesses a wide range of psychopathology, not just personality. The instrument underwent multiple rounds of rigorous psychometric testing in order to maximize scaling properties (e.g., internal consistency reliability, item-to-scale convergence and divergence, etc.) and has been shown to possess strong construct validity. All 344 items are rated by the patient along the same four point Likert scale (False, Slightly True, Mainly True, Very True), and are then summed (within scales) and converted to T scores relative to a general U.S. population sample. Another advantage of the PAI is that scores are also plotted relative to a large clinical sample, which allows clinicians to make additional interpretations about profile elevations relative to other psychiatric samples. The PAI includes four validity indices assessing inconsistent (INC) and idiosyncratic (INF) responding, as well as negative (NIM) and positive response styles (PIM). It also measures eleven clinical constructs (scales) including: Somatic Complaints (SOM), Anxiety (ANX), Anxiety-Related Disorders (ARD), Depression (DEP), Mania (MAN), Paranoia (PAR), Schizophrenia (SCZ), Borderline Features (BOR), Antisocial Features (ANT), Alcohol Problems (ALC), and Drug Problems (DRG). Finally, it contains five scales evaluating suicide risk and factors that may impact the course of treatment (e.g., treatment amenability, availability of social supports, etc.), as well interpersonal style (i.e., dominance and warmth). The PAI has been well validated across an array of clinical and nonclinical settings, and is frequently used in clinical and nonclinical (e.g., fertility clinics, employee evaluations) settings as a more comprehensive screening tool.

Table 7.8–4.
The Spectra: Indices of Psychopathology

Scale	No. of Items	Construct	Dimension/Spectrum
Depression (DEP)	6	Depressive affect and ideation	Internalizing
Anxiety (ANX)	8	Worry and fear of losing control	Internalizing
Social Anxiety (SOC)	5	Social worry and avoidance behavior	Internalizing
Post-Traumatic Stress (PTS)	6	Intrusive memories, physical reactivity, and avoidance	Internalizing
Alcohol Problems (ALC)	6	Negative effects of alcohol use	Externalizing
Drug Problems (DRG)	6	Negative effects of drug use	Externalizing
Severe Aggression (AGG)	6	Explosive anger and violence	Externalizing
Antisocial (ANTI)	8	Impulsivity, deceitfulness, rule breaking	Externalizing
Psychosis (PSY)	6	Hallucinations and delusions	Reality Impairing
Paranoid Ideation (PAR)	6	Persecutory thoughts	Reality Impairing
Manic Activation (MAN)	5	Mental and physical acceleration	Reality Impairing

The Spectra: Indices of Psychopathology (SPECTRA). The SPECTRA is a brief, self-administered multi-scale measure of psychopathology and functioning that was published in 2018 (Table 7.8–4). Guided by recent advances in hierarchical-dimensional models of psychopathology, it is comprised of 96 items which assess 12 lower-order clinical constructs: Depression, Anxiety, Social Anxiety, PTSD, Alcohol Problems, Drug Problems, Antisocial behavior, Severe Aggression, Psychosis, Paranoid Ideation, Manic Activation, and Grandiose Ideation. These clinical constructs were selected *a priori* based on multivariate research over the last several decades that has demonstrated their strong associations with three higher-order spectra (Internalizing [INT], Externalizing [EXT], and Reality Impairing [RI]) which explain the observed relationships (covariation) among common DSM disorders. These three spectra aggregate to constitute the General Psychopathology Index (GPI), which provides for an overall marker of psychiatric complexity or burden (also referred to as the *p-factor* in clinical research). The SPECTRA can be administered in paper and pencil format or electronically, and completed in 15 to 20 minutes. Norm-based scores are calculated for the clinical scales, spectra domains, and overall GPI—and these are based on a U.S. census-matched standardization sample of *N* = 1,064 adults. Research examining the psychometric properties of the SPECTRA have been quite promising, with potential application in outpatient, inpatient, and forensic contexts.

The SPECTRA is unlike other existing broadband measures of psychopathology (e.g., the MMPI and PAI) in several important ways. First, it has a new underlying hierarchical framework for psychopathology based on recent research, and provides quantitative measures that are interpretable at various levels (i.e., the specific clinical syndromes, the higher-order spectra, and the more global burden of illness) (Figure 7.8–1). This has implications not only for diagnostic efficiency, but also for treatment planning (where clinical disorders may be phenotypically similar or dissimilar) and clinical prediction (particularly in cases where complexity and burden are high). Second, whereas historically the DSM and ICD have traditionally conceptualized psychiatric disorders as discrete/categorical entities, which in turn influenced how classic broadband measures (e.g., MMPI, PAI) are interpreted (using specific cut-scores to denote clinical significance), the SPECTRA employs a dimensional approach to interpretation where scores up and down the continuum can be used to make clinical inferences irrespective of specific cut-scores. Third, in addition to the core clinical domains noted above, the SPECTRA also contains brief scales assessing suicidal ideation, general cognitive concerns, and adaptive psychological functioning. These ancillary scales may be helpful in assessing risk, screening for subjective cognitive complaints, and identifying psychological strengths (e.g., agency, interpersonal supports)—which may be relevant to treatment planning. Finally, on a more practical level, the SPECTRA also provides an efficient assessment of common psychopathology in a significantly shorter period of time as compared to the MMPI-3 and PAI—both of which are roughly 70% longer.

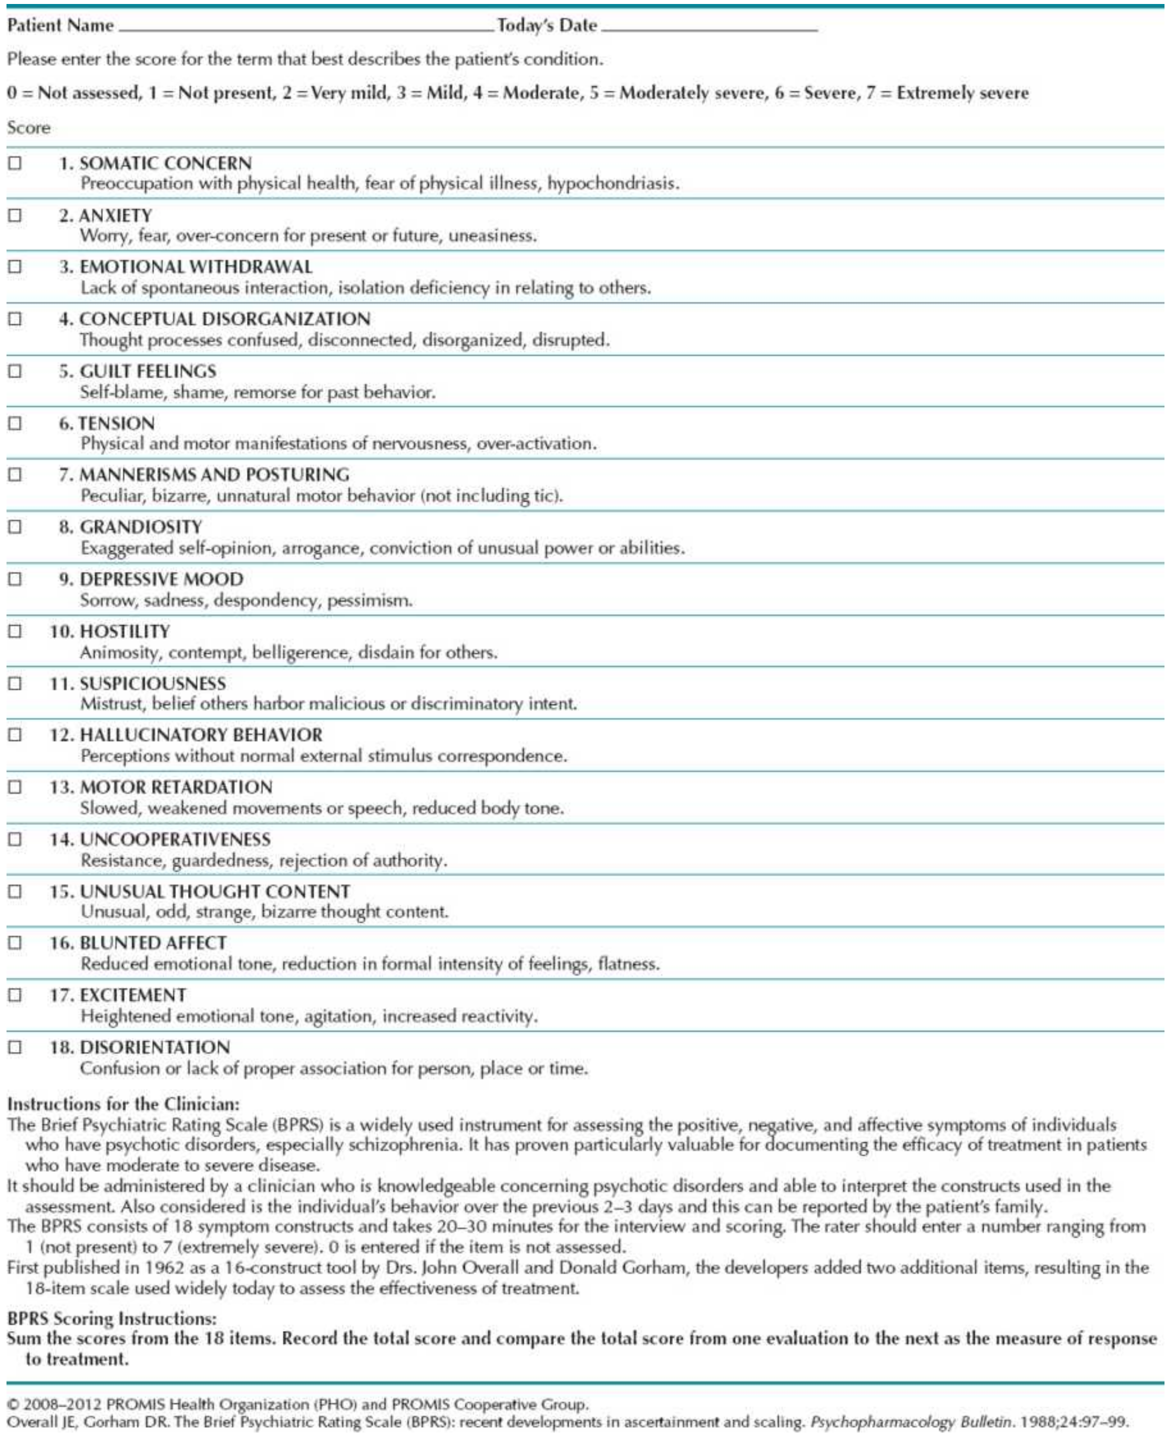
Schizophrenia Spectrum and Other Psychotic Disorders

A variety of instruments are used for patients with psychotic disorders. Those reported here are symptom severity measures. A developing consensus suggests that the distinction between positive (e.g., hallucinations and delusions) and negative symptoms (e.g., emotional blunting, social apathy, etc.) in schizophrenia is worthwhile, and more recently developed instruments implement this distinction. Because patients with psychotic disorders often lack insight and are sometimes agitated, observation of the patient is required in addition to direct questioning. Thus, most instruments in this domain must be administered by psychiatrists or others with clinical training.

Brief Psychiatric Rating Scale. The BPRS (Table 7.8–5) was developed in the late 1960s as a short scale for measuring the severity of psychiatric symptomatology. It was developed primarily to assess change in psychotic inpatients and covers a broad range of areas, including thought disturbance, emotional withdrawal and retardation, anxiety and depression, and hostility and suspiciousness. Its 18 items are rated on a seven-point item-specific Likert scale from 0 to 6, with the total score ranging from 0 to 108 (in some scoring systems, the lowest level for each item is 1, so the range is 18 to 126). Because the ratings include observations, as well as patient reports of symptoms, the BPRS can be used to rate patients with very severe impairment. It is intended for use by experienced clinicians and can be administered in 30 minutes or less, including patient interview and observation. Reliability of the BPRS is good to excellent when raters are experienced, but this is difficult to achieve without substantial training; a semi-structured interview and guide has been developed to increase reliability. Validity is also good as measured by correlations with other measures of symptom severity, especially those assessing schizophrenia symptomatology. The BPRS has been used extensively for decades as an outcome measure in treatment studies of schizophrenia; it functions well as a measure of change in this context and offers the advantage of comparability with earlier trials. However, it has been largely supplanted in more recent clinical trials by the newer measures described below. In addition, given its focus on psychosis and associated symptoms, it is only suitable for patients with fairly significant impairment. Its use in clinical practice is less well supported, in part because considerable training is required to achieve the necessary reliability.

Positive and Negative Syndrome Scale. The Positive and Negative Syndrome Scale (PANSS) was developed in the late 1980s to remedy perceived deficits in the BPRS in the assessment of positive and negative symptoms of schizophrenia and other psychotic disorders by adding additional items and providing careful anchors for each. The PANSS includes 30 items on three subscales: seven items covering positive symptoms, seven covering negative symptoms, and 16 covering general psychopathology (e.g., guilt, uncooperativeness). Each item is scored on a seven-point, item-specific Likert scale ranging from 1 to 7; thus, the positive and negative subscales each range from 7 to 49, and the general psychopathology scale ranges from 16 to 112. The PANSS requires a clinician rater because considerable probing and clinical judgment are required. A semi-structured interview guide is available. The ratings can be completed in 30 to 40 minutes. Reliability for each scale has been shown to be fairly high, with excellent internal consistency and interrater reliability. Validity also appears good based on correlation with other symptom severity measures and factor analytic validation of the subscales. The PANSS has become the standard tool for assessing clinical outcome in treatment studies of schizophrenia and other psychotic disorders and has been shown to be easy to administer reliably and sensitive to change with treatment. Its high reliability and good coverage of both positive and negative symptoms make it excellent for this purpose. It may also be useful for tracking severity in clinical practice, and its’ clear anchors make it easy to use in this setting.

Table 7.8–5.
Brief Psychiatric Rating Scale



Patient Name ______________________ Today's Date ______________

Please enter the score for the term that best describes the patient's condition.

0 = Not assessed, 1 = Not present, 2 = Very mild, 3 = Mild, 4 = Moderate, 5 = Moderately severe, 6 = Severe, 7 = Extremely severe

Score

☐ 1. SOMATIC CONCERN
Preoccupation with physical health, fear of physical illness, hypochondriasis.

☐ 2. ANXIETY
Worry, fear, over-concern for present or future, uneasiness.

☐ 3. EMOTIONAL WITHDRAWAL
Lack of spontaneous interaction, isolation deficiency in relating to others.

☐ 4. CONCEPTUAL DISORGANIZATION
Thought processes confused, disconnected, disorganized, disrupted.

☐ 5. GUILT FEELINGS
Self-blame, shame, remorse for past behavior.

☐ 6. TENSION
Physical and motor manifestations of nervousness, over-activation.

☐ 7. MANNERISMS AND POSTURING
Peculiar, bizarre, unnatural motor behavior (not including tic).

☐ 8. GRANDIOSITY
Exaggerated self-opinion, arrogance, conviction of unusual power or abilities.

☐ 9. DEPRESSIVE MOOD
Sorrow, sadness, despondency, pessimism.

☐ 10. HOSTILITY
Animosity, contempt, belligerence, disdain for others.

☐ 11. SUSPICIOUSNESS
Mistrust, belief others harbor malicious or discriminatory intent.

☐ 12. HALLUCINATORY BEHAVIOR
Perceptions without normal external stimulus correspondence.

☐ 13. MOTOR RETARDATION
Slowed, weakened movements or speech, reduced body tone.

☐ 14. UNCOOPERATIVENESS
Resistance, guardedness, rejection of authority.

☐ 15. UNUSUAL THOUGHT CONTENT
Unusual, odd, strange, bizarre thought content.

☐ 16. BLUNTED AFFECT
Reduced emotional tone, reduction in formal intensity of feelings, flatness.

☐ 17. EXCITEMENT
Heightened emotional tone, agitation, increased reactivity.

☐ 18. DISORIENTATION
Confusion or lack of proper association for person, place or time.

Instructions for the Clinician:

The Brief Psychiatric Rating Scale (BPRS) is a widely used instrument for assessing the positive, negative, and affective symptoms of individuals who have psychotic disorders, especially schizophrenia. It has proven particularly valuable for documenting the efficacy of treatment in patients who have moderate to severe disease.

It should be administered by a clinician who is knowledgeable concerning psychotic disorders and able to interpret the constructs used in the assessment. Also considered is the individual's behavior over the previous 2–3 days and this can be reported by the patient's family.

The BPRS consists of 18 symptom constructs and takes 20–30 minutes for the interview and scoring. The rater should enter a number ranging from 1 (not present) to 7 (extremely severe). 0 is entered if the item is not assessed.

First published in 1962 as a 16-construct tool by Drs. John Overall and Donald Gorham, the developers added two additional items, resulting in the 18-item scale used widely today to assess the effectiveness of treatment.

BPRS Scoring Instructions:

Sum the scores from the 18 items. Record the total score and compare the total score from one evaluation to the next as the measure of response to treatment.

© 2008–2012 PROMIS Health Organization (PHO) and PROMIS Cooperative Group.

Overall JE, Gorham DR. The Brief Psychiatric Rating Scale (BPRS): recent developments in ascertainment and scaling. *Psychopharmacology Bulletin*. 1988;24:97–99.

Scale for the Assessment of Positive Symptoms and Scale for the Assessment of Negative Symptoms. The Scale for the Assessment of Positive Symptoms (SAPS) and Scale for the Assessment of Negative

Symptoms (SANS) were designed to provide a detailed assessment of positive and negative symptoms of schizophrenia and may be used separately or in tandem. The domains assessed include hallucinations, delusions, bizarre behavior, and thought disorder for the SAPS and affective flattening, poverty of speech, apathy, anhedonia, and inattentiveness for the SANS. Each instrument consists of 30 fully anchored items each scored from 0 to 5; thus, the total score ranges from 0 to 150 for each. Each must be rated by an experienced clinician and requires approximately 30 minutes to complete. Good to excellent interrater reliability has been demonstrated for trained interviewers, and each scale has high internal consistency as well. Validity is supported by correlation with other symptom severity instruments. The SANS and SAPS are principally used to monitor treatment effects in clinical research and have also been used to help characterize positive and negative symptoms in studies of schizophrenia phenomenology. The SAPS has been to some extent supplanted by the PANSS, but the SANS still has a place in studies aimed at negative symptoms. The instruments are longer and more difficult to learn to use than the PANSS and thus generally too detailed for use in clinical practice. However, the comprehensive characterization of symptomatology provided might be useful as part of a formal evaluation.

Depressive Disorders

Rating depression depends, to a substantial extent, on subjective assessment of mood states, so interviews and self-report instruments are both common. Because depression is common in the general population and involves significant morbidity and even mortality, screening instruments—especially those using a self-report format—are potentially quite useful in primary care and community settings. A number of interviewer and self-administered instruments are described below.

Hamilton Rating Scale for Depression. The HAM-D was developed in the early 1960s to monitor the severity of major depression, with a focus on somatic symptomatology. The version in most common use has 17 items, although versions with different numbers of items (including the 24-item version) have been used in many studies as well. The 17-item version does not include some of the symptoms of depression in the DSM-III and its successors, most notably the so-called reverse neurovegetative signs (increased sleep, increased appetite, and psychomotor retardation).

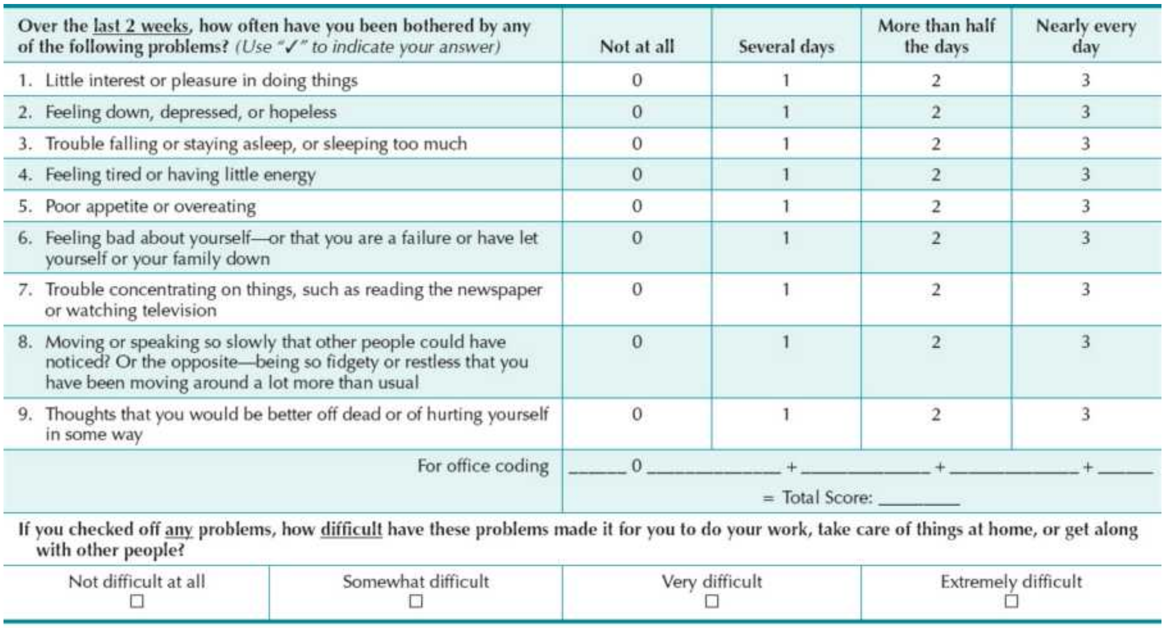
Items on the HAM-D are scored from 0 to 2 or from 0 to 4, with total score ranging from 0 to 50. Scores of 7 or less may be considered normal; 8 to 13, mild; 14 to 18, moderate; 19 to 22, severe; and 23 and above, very severe. The HAM-D was designed for clinician raters but has been used by trained lay administrators as well. Ratings are completed by the examiner based on patient interview and observations. A structured interview guide has been developed to improve reliability. The ratings can be completed in 15 to 20 minutes. Reliability is good to excellent, particularly when the structured interview version is used. Validity appears good based on correlation with other depression symptom measures. The HAM-D has been used extensively to evaluate change in response to pharmacologic and other interventions and thus offers the advantage of comparability across a broad range of treatment trials. It is more problematic in the older adults and the medically ill, in whom the presence of somatic symptoms may not be indicative of major depression.

Montgomery-Asberg Depression Rating Scale. The Montgomery-Asberg Depression Rating Scale (MADRS) was developed in 1979 explicitly for clinical trials, and thus was aimed at maximizing sensitivity to change in established depression. It can be administered by a psychiatrist, other physician, or psychiatric nurse, and a structured interview guide and self-report version are also available. It includes 10 items on seven-point, partially anchored, Likert scales. It can be administered in 10 to 15 minutes and is easy to use with minimal training. Very good reliability and validity have been demonstrated. Because of its sensitivity to change, the MADRS is frequently used in clinical trials of antidepressants and may also have a role in assessing the impact of treatment in clinical practice.

Beck Depression Inventory. The Beck Depression Inventory (BDI) was developed in the early 1960s to rate depression severity, with a focus on behavioral and cognitive dimensions of depression. The current version (the BDI-II) has added more coverage of somatic symptoms to be compatible with more current versions of the DSM and covers the most recent 2 weeks. Earlier versions are focused on the past week or even shorter intervals, which may be preferable for monitoring treatment response. The BDI includes 21 self-report items, each of which has four statements describing increasing levels of severity, and the total score ranges from 0 to 84. Scores of 0 to 9 are considered minimal; 10 to 16, mild; 17 to 29, moderate; and 30 to 63, severe. The scale can be completed in 5 to 10 minutes. Internal consistency has been high in numerous studies. Test–retest reliability is not consistently high, but this may reflect changes in underlying symptoms. Validity is supported by correlation with other depression measures. The principal use of the BDI is as an outcome measure in clinical trials of interventions for major depression, including psychotherapeutic interventions. Because it is a self-report instrument, it is sometimes used to screen for major depression. However, in trials of various cutoffs for a diagnosis of major depression, the best seemed to be 9, which had only fair sensitivity, at a cost of considerable nonspecificity, suggesting that the instrument has limited use for screening. The instrument's strength lies in measuring the depth of depression and in its comprehensive coverage of the cognitive dimension of depression.

The Patient Health Questionnaire-9-Item Screener for Depression. The Patient Health Questionnaire-9 (PHQ-9) is a nine-item, self-administered screening measure that was developed in 1999 (as part of the larger PHQ) as a brief tool for assessing depressive symptomatology in primary care settings (Table 7.8–6). The PHQ-9 items are rated along a four-point Likert scale (0. Not at all, 1. Several Days, 2. More than half of the days, and 3. Nearly every day) and then summed, with total scores ranging from 0 to 27. Although some have suggested cut-scores of 10 (or between 8 and 11) for a diagnosis of Major Depressive Disorder, the APA has also provided a system for interpreting different PHQ-9 score ranges in terms of severity: None = 0 to 4; Mild Depression = 5 to 9; Moderate Depression = 10–14; Moderately Severe Depression = 15 to 19; and Severe Depression = 20 to 27. The PHQ-9 in particular has generally performed well in terms of its underlying psychometric properties, and studies evaluating validity have also been promising. The APA has recommended the PHQ-9 as a brief screening tool for evaluating and tracking depressive symptomatology over time in DSM-5. A still shorter version, the PHQ-2, is also available as a depression screener, with more common application in primary care settings.

Table 7.8–6. The PHQ-9



Over the last 2 weeks, how often have you been bothered by any of the following problems? *(Use "✓" to indicate your answer)*	Not at all	Several days	More than half the days	Nearly every day
1. Little interest or pleasure in doing things	0	1	2	3
2. Feeling down, depressed, or hopeless	0	1	2	3
3. Trouble falling or staying asleep, or sleeping too much	0	1	2	3
4. Feeling tired or having little energy	0	1	2	3
5. Poor appetite or overeating	0	1	2	3
6. Feeling bad about yourself—or that you are a failure or have let yourself or your family down	0	1	2	3
7. Trouble concentrating on things, such as reading the newspaper or watching television	0	1	2	3
8. Moving or speaking so slowly that other people could have noticed? Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual	0	1	2	3
9. Thoughts that you would be better off dead or of hurting yourself in some way	0	1	2	3
For office coding	______ 0 ______	+ ______	+ ______	+ ______
	= Total Score: ________			

If you checked off any problems, how difficult have these problems made it for you to do your work, take care of things at home, or get along with other people?

Not difficult at all ☐	Somewhat difficult ☐	Very difficult ☐	Extremely difficult ☐

Developed by Drs. Robert L. Spitzer, Janet B.W. Williams, Kurt Kroenke and colleagues, with an educational grant from Pfizer Inc.

Inventory of Depressive Symptomatology and Quick Inventory of Depressive Symptomatology. The Inventory of Depressive Symptomatology (IDS) was developed in 1982 to reflect a broader conceptualization of major depression than the HAM-D and other earlier instruments and to provide a comprehensive assessment of depressed inpatients and outpatients. It has better coverage of the full nature and severity range of DSM-5 symptoms of depression. A shorter version, the 16-item Quick Inventory of Depressive Symptomatology (QUIDS), was released in 2000. Both clinician-rated (IDS-C and QUIDS-C) and self-report (IDS-SR and QUIDS-SR) versions of each instrument are available. The clinician versions come with structured interview guides to improve the reliability of the ratings. Each item has four to five scaled multiple-choice answers, ranging from no difficulty to significant difficulty in that area. The IDS-SR requires 15 to 20 minutes, and the IDS-C 20 to 30 minutes; the corresponding versions of the QUIDS can be completed in half the time. The IDS has been subjected to rigorous reliability and validity assessment. It shows good reliability in a variety of paradigms and excellent validity, as judged by comparison with other depression scales. It has also been shown to have good validity in the classification of depressive subtypes and to be more sensitive to the milder end of the spectrum than older depression instruments. The QUIDS also has very good reliability and validity but does not attempt to measure subtypes. Both instruments have considerable utility in clinical research and clinical practice for the evaluation of depression and assessment of its response to treatment.

Bipolar and Related Disorders

In evaluating mania, as for psychotic disorders, limited insight and agitation may hinder accurate symptom reporting, so clinician ratings including observational data are generally required. Likewise, whether someone is actively experiencing symptoms of mania/hypomania at the point of evaluation may also affect whether and how current and past manic symptoms are endorsed on psychometric tools, and thus a careful retrospective analysis via clinical interview is also recommended to more systematically rule this out. A patient who accurately reports *no* symptoms of mania at the time of evaluation may in fact have a history of mania in the past and meet criteria for Bipolar Disorder—reflecting the episodic nature of these symptoms. A number of instruments that assess for mania/hypomania are summarized below.

Young Mania Rating Scale. The Young Mania Rating Scale (YMRS) is a checklist developed in the late 1970s to provide a brief but thorough evaluation of the severity of mania that could be used to monitor treatment response or detect relapse. It consists of a checklist of 11 items rated either from 0 to 4 (seven items) or from 0 to 8 (four items). Each item has five item-specific anchors. The total score ranges from 0 to 60. Ratings include clinical observation, so it must be rated by a clinician, but reliable ratings have been obtained by nurses on inpatient units and beginning psychiatric residents. Reliability is good based on interrater reliability and internal consistency studies. Validity also appears to be good based on limited data on correlation with other mania measures. The YMRS is useful for evaluating response to treatment in clinical research, and it has been found to be sensitive to change in this setting. It might also be used to assess treatment response or to monitor for relapse in treated or untreated patients, although extensive experience with this use has not been reported.

The Altman Self-Rating Mania Scale (ASRM). The Altman Self-Rating Mania Scale (ASRM) was initially developed in the late 1990s by Altman and colleagues, and consists of five items which assess the presence and/or severity of manic symptoms (Table 7.8–7). Items are rated along unique five-point Likert scales, where patients are asked to rate their symptoms with respect to the last 7 days. In cases where patients may be too impaired to complete the tool, an informant version is also available. Total scores range from 5 to 25, where higher scores are suggestive of greater pathology. Scores of 6 or higher have been shown to be associated with a higher probability of a manic or hypomanic condition, and may signal the need for further evaluation and/or treatment. The ASRM has been shown to possess strong psychometric properties (including test–retest and internal consistency reliability), as well good convergent and discriminant validity (e.g., discriminating patient groups who are manic from other kinds of psychiatric disorders). The ASRM has also been found to be sensitive to change as a function of pharmacotherapy. The APA has recommended the ASRM as a brief measure for assessing mania/hypomania in the Emerging Measures section of the DSM-5.

Anxiety Disorders

The anxiety disorders addressed by the measures below include panic disorder and generalized anxiety disorder. When anxiety measures are examined, it is important to be aware that there have been changes over time in how anxiety disorders are defined. For example, Post Traumatic Stress Disorder (PTSD) and Obsessive-Compulsive Disorders are no longer included in the DSM-5's Anxiety Disorders section, and generalized anxiety disorder has shifted somewhat to focus more on the affective (worry, fear) dimension of the condition. Thus, older measures have somewhat less relevance for diagnostic purposes, although they may identify symptoms causing considerable distress. Whether reported during an interview or on a self-report rating scale, virtually all measures in this domain, like the measures of depression discussed above, depend on subjective descriptions of inner states.

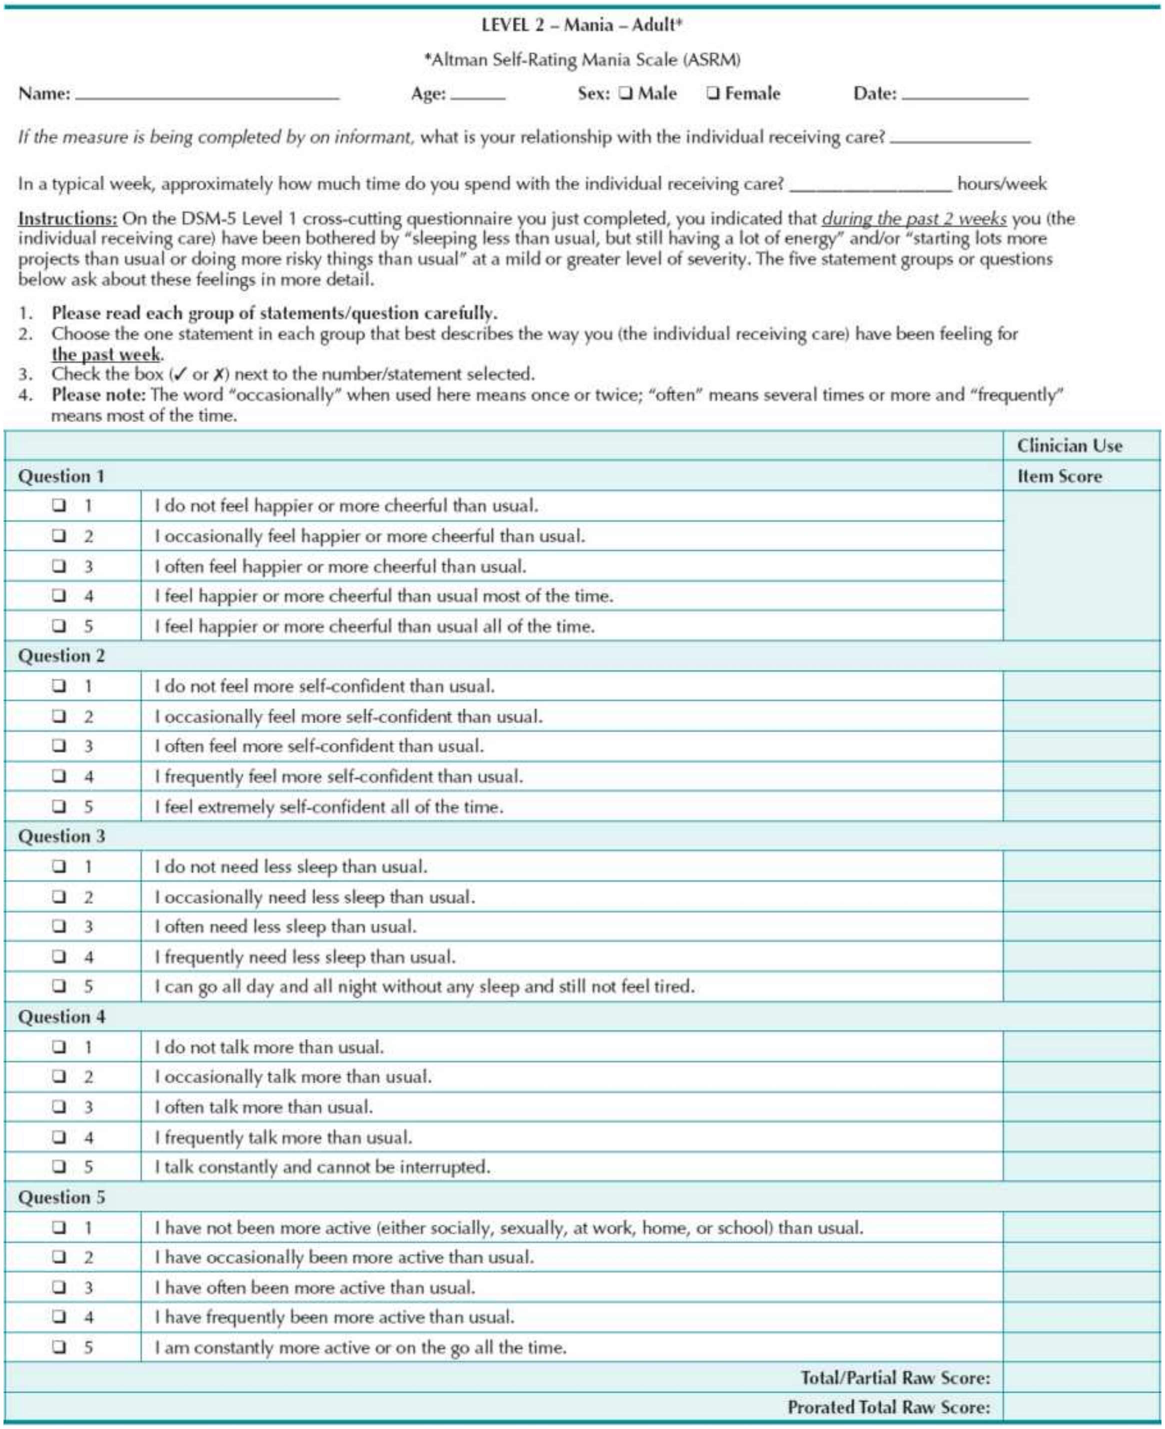
Hamilton Anxiety Rating Scale. The HAM-A was developed in the late 1950s to assess anxiety symptoms, both somatic and cognitive. Because the conceptualization of anxiety has changed considerably, the HAM-A provides limited coverage of the “worry” required for a DSM-5 diagnosis of generalized anxiety disorder and does not include the episodic anxiety found in panic disorder. There are 14 items, each of which is rated from 0 to 4 on an unanchored severity scale, with the total score ranging from 0 to 56. A score of 14 has been suggested as the threshold for clinically significant anxiety, but scores of 5 or less are typical in individuals in the community. The scale is designed to be administered by a clinician, and formal training or the use of a structured interview guide is required to achieve high reliability. A computer-administered version is also available. Reliability is fairly good based on internal consistency, interrater, and test–retest studies. However, given the lack of specific anchors, reliability should not be assumed to be high across different users in the absence of formal training. Validity appears good based on correlation with other anxiety scales but is limited by the relative lack of coverage of domains critical to the modern understanding of anxiety disorders. Even so, the HAM-A has been used extensively to monitor treatment response in clinical trials of generalized anxiety disorder and may also be useful for this purpose in clinical settings.

The Generalized Anxiety Disorder-7. The Generalized Anxiety Disorder-7 (GAD-7) is a seven-item, self-administered measure that was published in 2006 as a general screening measure for symptoms of generalized anxiety. It consists of seven items that inquire about general worry and fear symptoms in the last 2 weeks, all of which are rated along a four-point Likert scale (0. Not at all, 1. Several Days, 2. More than half the days, and 3. Nearly every day). Scores range from 0 to 21 (where higher scores indicate greater levels of symptomatology), and cut-scores of 5, 10, and 15 have been suggested for mild, moderate, and severe GAD, respectively. The GAD-7 has been found to possess strong psychometric properties, and its use in clinical practice has increased in recent years. That being said, although it remains a useful tool for evaluating more generalized symptoms of anxiety, it may not provide the same type of correspondence to a DSM-5-TR diagnosis given differences in timeframe (the GAD-7 asks about symptoms in the last 2 weeks, whereas DSM-5 requires that symptoms be present more days than not for 6 months) and DSM-5’s greater emphasis on the affective dimension of worry/fear.

The Patient-Reported Outcomes Measurement Information System Emotional Distress—Anxiety Short-Form. The Patient-Reported Outcomes Measurement Information System (PROMIS) Emotional Distress—Anxiety Short-Form is a seven-item measure of generalized symptoms of anxiety and worry that was developed by the larger PROMIS. PROMIS was launched in 2004 by the National Institute of Health (NIH) in an effort to develop psychometrically sound measures of patient-reported measures of physical health, mental well-being, and social functioning. Items from the PROMIS Emotional Distress—Anxiety Short-Form are rated along the same five-point Likert scale and then summed, with total scores ranging from 7 to 35. These raw (sum) scores are then converted into T scores using a conversion table provided by PROMIS, which allows for immediate comparison relative to the general population. There are measures available for both adults (18+) and children (6 to 17). The PROMIS Emotional Distress—Anxiety Short-Form has demonstrated strong preliminary reliability and validity and was recommended for use in assessing anxiety in DSM-5, although given its more recent development, additional research is needed to substantiate this research base before widespread adoption.

Panic Disorder Severity Scale. The Panic Disorder Severity Scale (PDSS) was developed in the 1990s as a brief rating scale for the severity of panic disorder. It was based on the Yale-Brown Obsessive-Compulsive Scale (YBOCS) and has seven items, each of which is rated on an item-specific, five-point Likert scale. The seven items address frequency of attacks, distress associated with attacks, anticipatory anxiety, phobic avoidance, and impairment. The items are scored from 0 to 4, and the total score ranges from 0 to 28. The instrument was designed for use by clinicians, but a self-report version is also available. Reliability is excellent based on interrater studies, but in keeping with the small number of items and multiple dimensions, internal consistency is limited. Validity is supported by correlations with other anxiety measures, both at the total and item level; lack of correlation with the HAM-D; and, more recently, by brain imaging studies. Growing experience with the PDSS suggests that it is sensitive to change with treatment and is useful as a change measure in clinical trials or other outcome studies for panic disorder, as well as for monitoring panic disorder in clinical practice.

Table 7.8–7.
The Altman Self Rating Mania Scale (ASRM)



LEVEL 2 – Mania – Adult*

*Altman Self-Rating Mania Scale (ASRM)

Name: ______________________________ **Age:** ______ **Sex:** ☐ Male ☐ Female **Date:** ______________

If the measure is being completed by an informant, what is your relationship with the individual receiving care? ________________

In a typical week, approximately how much time do you spend with the individual receiving care? __________________ hours/week

Instructions: On the DSM-5 Level 1 cross-cutting questionnaire you just completed, you indicated that *during the past 2 weeks* you (the individual receiving care) have been bothered by "sleeping less than usual, but still having a lot of energy" and/or "starting lots more projects than usual or doing more risky things than usual" at a mild or greater level of severity. The five statement groups or questions below ask about these feelings in more detail.

1. **Please read each group of statements/question carefully.**
2. Choose the one statement in each group that best describes the way you (the individual receiving care) have been feeling for **the past week**.
3. Check the box (✓ or ✗) next to the number/statement selected.
4. **Please note:** The word "occasionally" when used here means once or twice; "often" means several times or more and "frequently" means most of the time.

		Clinician Use
Question 1		**Item Score**
☐ 1	I do not feel happier or more cheerful than usual.	
☐ 2	I occasionally feel happier or more cheerful than usual.	
☐ 3	I often feel happier or more cheerful than usual.	
☐ 4	I feel happier or more cheerful than usual most of the time.	
☐ 5	I feel happier or more cheerful than usual all of the time.	
Question 2		
☐ 1	I do not feel more self-confident than usual.	
☐ 2	I occasionally feel more self-confident than usual.	
☐ 3	I often feel more self-confident than usual.	
☐ 4	I frequently feel more self-confident than usual.	
☐ 5	I feel extremely self-confident all of the time.	
Question 3		
☐ 1	I do not need less sleep than usual.	
☐ 2	I occasionally need less sleep than usual.	
☐ 3	I often need less sleep than usual.	
☐ 4	I frequently need less sleep than usual.	
☐ 5	I can go all day and all night without any sleep and still not feel tired.	
Question 4		
☐ 1	I do not talk more than usual.	
☐ 2	I occasionally talk more than usual.	
☐ 3	I often talk more than usual.	
☐ 4	I frequently talk more than usual.	
☐ 5	I talk constantly and cannot be interrupted.	
Question 5		
☐ 1	I have not been more active (either socially, sexually, at work, home, or school) than usual.	
☐ 2	I have occasionally been more active than usual.	
☐ 3	I have often been more active than usual.	
☐ 4	I have frequently been more active than usual.	
☐ 5	I am constantly more active or on the go all the time.

Trauma and Stressor-Related Disorders

With the reorganization of DSM-5, Trauma and Stressor-Related Disorders were moved out of the Anxiety Disorders section and given their own distinct section—which now focuses on an array of conceptually similar disorders in which exposure to a stressful or traumatic event is a necessary criterion. These include Reactive Attachment Disorder, Disinhibited Social Engagement Disorder, PTSD, Acute Stress Disorder, and Adjustment Disorders. PTSD remains the most commonly studied of these disorders, and a PTSD instrument is described here.

Clinician-Administered PTSD Scale. The Clinician-Administered PTSD Scale (CAPS) was developed in 1990 to operationalize the DSM-III-R diagnosis of PTSD and can easily be modified to obtain a diagnosis by DSM-5 criteria. The interview includes 17 items required to make the diagnosis, covering all four criteria: (1) the event itself, (2) reexperiencing of the event, (3) avoidance, and (4) increased arousal. For each of the 17 items, the interviewer rates both the frequency and the intensity on a five-point scale ranging from 0 to 4. The diagnosis requires evidence of a traumatic event, one symptom of reexperiencing, three of avoidance, and two of arousal (typically, an item is counted if frequency is at least 1 and intensity is at least 2). The items can also be used to generate a total PTSD severity score obtained by summing the frequency and intensity scales for each item. The CAPS also includes several global rating scales for the impact of PTSD symptomatology on social and occupational functioning, for general severity, for recent changes, and for the validity of the patient's report. The CAPS must be administered by a trained clinician and requires 45 to 60 minutes to complete, with follow-up examinations somewhat briefer. It has demonstrated reliability and validity in multiple settings and multiple languages, and performs well in the research setting for diagnosis and severity assessment, but is generally too lengthy for use in clinical practice.

The PTSD Checklist for DSM-5. The PTSD Checklist for DSM-5 (PCL-5) is a 20-item self-report instrument that assesses DSM-5 symptoms of PTSD (Table 7.8–8). While structured clinical interviews such as the SCID or CAPS (described above) are the gold standard for making a formal diagnosis of PTSD, the PCL-5 may be useful in a number of contexts—whether for symptom monitoring, screening, or in making provisional diagnoses. The PCL-5 takes roughly 5 to 10 minutes to complete, and is scored by summing the 20 items. Cut scores between 31 and 33 have been suggested as indicative of “probable PTSD.” Of note, the PCL-5 items are organized according to DSM-5 symptom clusters for PTSD (e.g., items 1 to 5 measure PTSD Cluster B symptoms, items 6 to 7 measure PTSD Cluster C symptoms, etc.). As a result, the developers suggest clinicians may use the PCL-5 to make provisional PTSD diagnoses based on the number of symptoms endorsed within these discrete domains. Finally, multiple versions of the PCL-5 are available, including civilian and military forms, and those that are trauma-specific. The psychometric properties of the PCL-5 have been shown to be robust, which may explain its popularity in contexts where symptom tracking is a priority.

Obsessive Compulsive and Related Disorders

Like the Trauma and Stressor-Related Disorders, Obsessive Compulsive Disorder and Related Disorders were also removed from the Anxiety Disorders section and given their own section in DSM-5. This new family of disorders now includes: Obsessive Compulsive Disorder, Body Dysmorphic Disorder, Hoarding Disorder, Trichotillomania, and Excoriation, among others. However, OCD remains the most common and researched of these disorders, and several rating instruments for OCD are summarized below.

Yale-Brown Obsessive-Compulsive Scale. The YBOCS was developed in the late 1980s to measure the severity of symptoms in OCD. It has 10 items rated based on a semi-structured interview. The first five items concern obsessions: The amount of time that they consume, the degree to which they interfere with normal functioning, the distress that they cause, the patient’s attempts to resist them, and the patient’s ability to control them. The remaining five items ask parallel questions about compulsions. Each item has a set of item-specific anchors scored from 0 to 4, so total scores for obsessions and compulsions each range from 0 to 20, and overall total score ranges from 0 to 40. Typical scores for patients with OCD are in the 16 to 30 range, and a threshold of 16 is typically used for inclusion in drug trials. The semi-structured interview and ratings can be completed in 15 minutes or less. A self-administered version can be completed in 10 to 15 minutes. Computerized and telephone use have also been found to provide acceptable ratings. Before the first use of the YBOCS, an associated 64-item checklist is administered to provide a more detailed assessment of the specific content of the patient’s obsessions and delusions. Reliability studies of the YBOCS show good internal consistency, interrater reliability, and test–retest reliability over a 1-week interval. The YBOCS has become the standard instrument for assessing OCD severity and is used in virtually every drug trial. It may also be used clinically to monitor treatment response.

The Repetitive Thoughts and Behaviors Scale. The Repetitive Thoughts and Behaviors Scale was adapted from the Florida Obsessive Compulsive Inventory (FOCI), published in 1994, and consists of five items rated by patients along item-specific five-point (0 to 4) Likert scales that are summed for a total score ranging from 0 to 20—with higher scores suggestive of more intense repetitive thoughts/behaviors. A cut-score of 8 has been suggested as a threshold for more intensive inquiry into potential obsessions/compulsions, and clinicians have also been encouraged to average the five items as a means of obtaining an overall estimate of severity (where 0 = mild; 1 = moderate; 2 = severe; and 3 = extreme). The Repetitive Thoughts and Behaviors scale has shown good initial reliability and validity, but, as with other DSM-5 emerging measures, future research will be helpful in further elucidating the scale's properties and clinical application.

Substance-Related and Addictive Disorders

DSM-5 now organizes substance-related disorders in a way that combines previous distinctions of "abuse" and "dependence" along a common continuum from mild to severe, and focuses on 10 separate classes of substances as separate use disorders: alcohol; caffeine; cannabis; hallucinogens; inhalants; opioids; sedatives, hypnotics, and anxiolytics; stimulants; tobacco; and other (unknown) substances. These disorders, particularly those involving alcohol, are common and debilitating in the general population, so screening instruments are particularly helpful. Because these behaviors are socially undesirable, underreporting of symptoms is a significant problem; thus, the validity of all substance use measures is limited by the honesty of the patient. Validation against drug tests or other measures is of great value, particularly when working with patients who have known substance abuse.

Table 7.8–8.
The PTSD Checklist for DSM-5 (PCL-5)

PCL-5 with Criterion A

Instructions: This questionnaire asks about problems you may have had after a very stressful experience involving actual or threatened death, serious injury, or sexual violence. It could be something that happened to you directly, something you witnessed, or something you learned happened to a close family member or close friend. Some examples are a serious accident; fire; disaster such as a hurricane, tornado, or earthquake; physical or sexual attack or abuse; war; homicide; or suicide.

First, please answer a few questions about your worst event, which for this questionnaire means the event that currently bothers you the most. This could be one of the examples above or some other very stressful experience. Also, it could be a single event (for example, a car crash) or multiple similar events (for example, multiple stressful events in a war-zone or repeated sexual abuse).

Briefly identify the worst event (if you feel comfortable doing so):

How long ago did it happen? ________________________________ (please estimate if you are not sure)

Did it involve actual or threatened death, serious injury, or sexual violence?
_____ Yes
_____ No

How did you experience it?
_____ It happened to me directly
_____ I witnessed it
_____ I learned about it happening to a close family member or close friend
_____ I was repeatedly exposed to details about it as part of my job (for example, paramedic, police, military, or other first responder)
_____ Other, please describe

If the event involved the death of a close family member or close friend, was it due to some kind of accident or violence, or was it due to natural causes?
_____ Accident or violence
_____ Natural causes
_____ Not applicable (the event did not involve the death of a close family member or close friend)

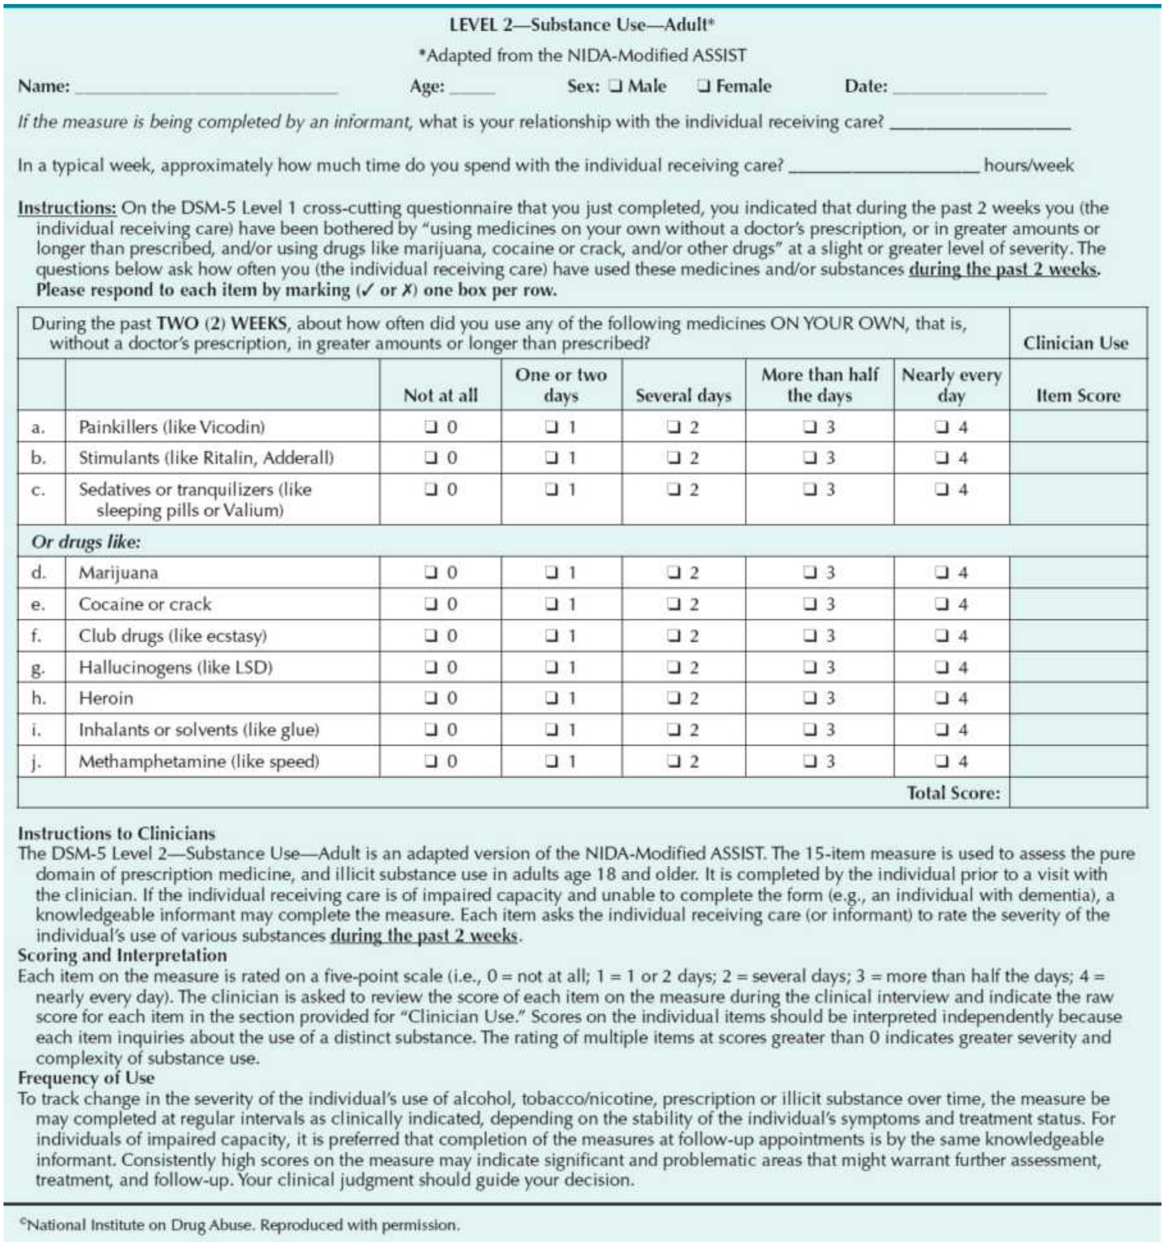
Second, below is a list of problems that people sometimes have in response to a very stressful experience. Keeping your worst event in mind, please read each problem carefully and then circle one of the numbers to the right to indicate how much you have been bothered by that problem in the past month.

In the past month, how much were you bothered by:	Not at all	A little bit	Moderately	Quite a bit	Extremely
1. Repeated, disturbing, and unwanted memories of the stressful experience?	0	1	2	3	4
2. Repeated, disturbing dreams of the stressful experience?	0	1	2	3	4
3. Suddenly feeling or acting as if the stressful experience were actually happening again (as if you were actually back there reliving it)?	0	1	2	3	4
4. Feeling very upset when something reminded you of the stressful experience?	0	1	2	3	4
5. Having strong physical reactions when something reminded you of the stressful experience (for example, heart pounding, trouble breathing, sweating)?	0	1	2	3	4
6. Avoiding memories, thoughts, or feelings related to the stressful experience?	0	1	2	3	4
7. Avoiding external reminders of the stressful experience (for example, people, places, conversations, activities, objects, or situations)?	0	1	2	3	4
8. Trouble remembering important parts of the stressful experience?	0	1	2	3	4
9. Having strong negative beliefs about yourself, other people, or the world (for example, having thoughts such as: I am bad, there is something seriously wrong with me, no one can be trusted, the world is completely dangerous)?	0	1	2	3	4
10. Blaming yourself or someone else for the stressful experience or what happened after it?	0	1	2	3	4
11. Having strong negative feelings such as fear, horror, anger, guilt, or shame?	0	1	2	3	4
12. Loss of interest in activities that you used to enjoy?	0	1	2	3	4
13. Feeling distant or cut off from other people?	0	1	2	3	4
14. Trouble experiencing positive feelings (for example, being unable to feel happiness or have feelings for people close to you)?	0	1	2	3	4
15. Irritable behavior, angry outbursts, or acting aggressively?	0	1	2	3	4
16. Taking too many risks or doing things that could cause you harm?	0	1	2	3	4
17. Being "superalert" or watchful or on guard?	0	1	2	3	4
18. Feeling jumpy or easily startled?	0	1	2	3	4
19. Having difficulty concentrating?	0	1	2	3	4
20. Trouble falling or staying asleep?	0	1	2	3	4

From Weathers FW, Litz BT, Keane TM, et al. *The PTSD Checklist for DSM-5 (PCL-5)—Extended Criterion A [Measurement instrument]*. National Center for PTSD; 2013. https://www.ptsd.va.gov

The Level 2 Substance Abuse Module from the DSM-5. The Level 2 Substance Abuse Module from the DSM-5 is a modified version of the National Institute on Drug Abuse's ASSIST evaluation system and was developed as a brief screener to augment the clinical interview when evaluating for potential substance misuse (Table 7.8–9). The 10-item measure is completed either by the patient or informant prior to meeting with a clinician, takes roughly 5 to 10 minutes, and asks about how frequently the patient has used various classes of substances in the last two weeks on a five-point Likert scale (0, not at all; 1, 1 or 2 days; 2, several days; 3, more than half the days; 4, nearly every day). Clinicians are advised to interpret each item separately given that each assesses use of a different substance. Although no formal scoring program exists, higher scores are indicative of greater complexity and severity of substance use, and suggest the need for further evaluation and treatment. The APA has recommended this measure in the DSM-5's Emerging Measures section as one method for evaluating and tracking substance misuse over time, although validity and reliability data is somewhat limited given its more recent release.

Table 7.8–9.
The Level 2 Substance Use Module from DSM-5



LEVEL 2—Substance Use—Adult*

*Adapted from the NIDA-Modified ASSIST

Name: ____________________ **Age:** _____ **Sex:** ☐ **Male** ☐ **Female** **Date:** ______________

If the measure is being completed by an informant, what is your relationship with the individual receiving care? ______________

In a typical week, approximately how much time do you spend with the individual receiving care? ______________ hours/week

Instructions: On the DSM-5 Level 1 cross-cutting questionnaire that you just completed, you indicated that during the past 2 weeks you (the individual receiving care) have been bothered by "using medicines on your own without a doctor's prescription, or in greater amounts or longer than prescribed, and/or using drugs like marijuana, cocaine or crack, and/or other drugs" at a slight or greater level of severity. The questions below ask how often you (the individual receiving care) have used these medicines and/or substances **during the past 2 weeks**. **Please respond to each item by marking (✓ or ✗) one box per row.**

During the past **TWO (2) WEEKS**, about how often did you use any of the following medicines ON YOUR OWN, that is, without a doctor's prescription, in greater amounts or longer than prescribed?							Clinician Use
		Not at all	One or two days	Several days	More than half the days	Nearly every day	Item Score
a.	Painkillers (like Vicodin)	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
b.	Stimulants (like Ritalin, Adderall)	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
c.	Sedatives or tranquilizers (like sleeping pills or Valium)	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
Or drugs like:							
d.	Marijuana	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
e.	Cocaine or crack	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
f.	Club drugs (like ecstasy)	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
g.	Hallucinogens (like LSD)	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
h.	Heroin	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
i.	Inhalants or solvents (like glue)	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
j.	Methamphetamine (like speed)	☐ 0	☐ 1	☐ 2	☐ 3	☐ 4	
						Total Score:	

Instructions to Clinicians

The DSM-5 Level 2—Substance Use—Adult is an adapted version of the NIDA-Modified ASSIST. The 15-item measure is used to assess the pure domain of prescription medicine, and illicit substance use in adults age 18 and older. It is completed by the individual prior to a visit with the clinician. If the individual receiving care is of impaired capacity and unable to complete the form (e.g., an individual with dementia), a knowledgeable informant may complete the measure. Each item asks the individual receiving care (or informant) to rate the severity of the individual's use of various substances **during the past 2 weeks**.

Scoring and Interpretation

Each item on the measure is rated on a five-point scale (i.e., 0 = not at all; 1 = 1 or 2 days; 2 = several days; 3 = more than half the days; 4 = nearly every day). The clinician is asked to review the score of each item on the measure during the clinical interview and indicate the raw score for each item in the section provided for "Clinician Use." Scores on the individual items should be interpreted independently because each item inquiries about the use of a distinct substance. The rating of multiple items at scores greater than 0 indicates greater severity and complexity of substance use.

Frequency of Use

To track change in the severity of the individual's use of alcohol, tobacco/nicotine, prescription or illicit substance over time, the measure be may completed at regular intervals as clinically indicated, depending on the stability of the individual's symptoms and treatment status. For individuals of impaired capacity, it is preferred that completion of the measures at follow-up appointments is by the same knowledgeable informant. Consistently high scores on the measure may indicate significant and problematic areas that might warrant further assessment, treatment, and follow-up. Your clinical judgment should guide your decision.

CAGE. The CAGE was developed in the mid-1970s to serve as a very brief screen for significant alcohol problems in a variety of settings, which could then be followed up by clinical inquiry. CAGE is an acronym for the four questions that comprise the instrument: (1) Have you ever felt you should *c*ut down on your drinking? (2) Have people *a*nnoyed you by criticizing your drinking? (3) Have you ever felt bad or *g*uilty about your drinking? (4) Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (*e*ye-opener)? Each “yes” answer is scored as 1, and these are summed to generate a total score. Scores of 1 or more warrant follow-up, and scores of 2 or more strongly suggest significant alcohol problems. The instrument can be administered in a minute or less, either orally or on paper. Reliability has not been formally assessed. Validity has been assessed against a clinical diagnosis of alcohol abuse or dependence, and these four questions perform surprisingly well. Using a threshold score of 1, the CAGE achieves excellent sensitivity and fair to good specificity. A threshold of 2 provides still greater specificity but at the cost of a fall in sensitivity. The CAGE performs well as an extremely brief screening instrument for use in primary care or in psychiatric practice focused on problems unrelated to alcohol. However, it has limited ability to pick up early indicators of problem drinking that might be the focus of preventive efforts.

Alcohol Use Disorders Identification Test. The Alcohol Use Disorders Identification Test (AUDIT) was developed by the WHO in the late 1980s as a brief screening instrument designed for the early detection of hazardous (i.e., involving the risk of harm) and harmful (i.e., involving the presence of harm) alcohol use in a variety of settings. It focuses on both the past year and current drinking. It includes a 10-item core screening instrument covering alcohol consumption, drinking behaviors, and alcohol-related problems. Each item is rated using item-specific anchors scored from 0 to 4 and summed for a total score from 0 to 40. The AUDIT can be administered and scored in less than 5 minutes and does not require professional training. The AUDIT also offers a clinical screening procedure involving a physical examination and blood tests, which adds no more than 5 to 10 minutes to a routine medical examination. Reliability of the AUDIT appears good based on internal consistency data. Validity judged against a clinical diagnosis of alcoholism is also good: Using a threshold score of 8 is quite sensitive, at least in men, but somewhat nonspecific; less stringent cutoffs may perform better for women and adolescents. A score of 10 is more specific but at a cost in specificity. Validity also appears good based on correlation with other alcohol self-report measures and risk factors for alcoholism. The AUDIT provides an excellent brief screen for alcohol problems and is particularly good for detecting problem drinking at a fairly mild stage. However, its focus on early detection of hazardous and harmful drinking makes it less suitable to use as a diagnostic instrument.

Drug Abuse Screening Test. The Drug Abuse Screening Test (DAST) was developed in the early 1980s to serve as a screening and assessment instrument for drug abuse. The DAST is an adaptation of the Michigan Alcohol Screening Test (MAST) used to screen for alcoholism. It focuses on lifetime drug use, so it is not designed to measure changes over time. The current version of the DAST has 20 yes–no items, and can be given orally or as a paper-and-pencil questionnaire. An earlier version had 28 items, so the 20-item version is sometimes called the *Brief DAST.* The positive items can be summed to form a 20-point scale. The DAST can be administered and scored in less than 10 minutes. Reliability, based on internal consistency, is very good. Validity, based on ability to detect drug abuse disorder, also appears high, with excellent sensitivity and fairly good specificity using a threshold score of 5. The DAST is useful as a screening tool for drug abuse problems in patients with other mental disorders, particularly alcohol abuse. It also provides an overview of problem severity that may be useful to guide treatment choices. However, because it takes a lifetime approach, it is not useful as a change measure in clinical practice or clinical trials.

Addiction Severity Index. The Addiction Severity Index (ASI) was developed in the early 1980s to serve as a quantitative measure of symptoms and functional impairment due to alcohol or drug disorders. It covers demographics, alcohol use, drug use, psychiatric status, medical status, employment, legal status, and family and social issues. Frequency, duration, and severity are assessed. It has 142 items in varying formats, including yes–no, multiple-choice, and scaled items. It includes both subjective and objective items reported by the patient and observations made by the interviewer. In each area, the ASI yields the rater's global assessment of severity, along with a computer score on a 0 to 1 scale. The 142-item version includes information on the past 30 days and lifetime status, but a shorter version is available for use at follow-up. The instrument is designed for clinician administration but has been used successfully by trained lay raters. Training is recommended, and both manuals and formal training programs are available. A computerized version is also available. The standard ASI requires 45 to 75 minutes to complete, but the follow-up version can be completed in 15 to 20 minutes.

Very good to excellent reliability has been demonstrated for the overall composite score, with somewhat lower reliability for severity ratings in each area. Validity has also been demonstrated based on correlation with other measures and discrimination of patient from nonpatient populations. Normative data are available for a range of populations of alcohol and drug abusers, including alcohol clinic patients, drug abusers, homeless persons, and prisoners. The principal use of the ASI is as an aid to treatment planning and the assessment of treatment outcome in clinical and law enforcement settings. It is relatively time-consuming to administer but performs well for this purpose. It has also been used in clinical research as a sensitive indicator of baseline severity and change over time, which allows comparison between clinical research and clinical practice.

Eating Disorders

Although feeding and eating disorders share a number of psychological and behavioral features, the DSM-5 has expanded the framework for conceptualizing and diagnosing these disorders based on differences in classification, clinical course, and treatment outcome, and as a means of reducing the frequency of the Eating Disorder NOS diagnosis. DSM-5 includes the following: Pica, Rumination Disorder, avoidant/restrictive food intake, disorder, anorexia nervosa, bulimia nervosa, and binge-eating disorder. A wide variety of instruments, particularly self-report scales, are available. Because of the secrecy that may surround dieting, bingeing, purging, and other symptoms, validation against other indicators (e.g., body weight for anorexia or dental examination for bulimia) may be very helpful. Such validation is particularly critical for patients with anorexia, who may lack insight into their difficulties.

Eating Disorders Examination. The Eating Disorders Examination (EDE) was developed in 1987 as the first interviewer-based comprehensive assessment of eating disorders, including diagnosis, severity, and an assessment of subthreshold symptoms, and a 2014 revision (version 17.0) was developed to be compatible with DSM-5. A self-report version (the EDE-Q), as well as an interview for children, has since been developed. The EDE focuses on symptoms during the preceding 4 weeks, although longer-term questions are included to assess diagnostic criteria for eating disorders. Each item on the EDE has a required probe with suggested follow-up questions to judge severity or frequency or both, which are then rated on a seven-point Likert scale. For the self-report version, subjects are asked to make similar ratings of frequency or severity. The instrument provides both global severity ratings and ratings on four subscales: restraint, eating concern, weight concern, and shape concern. The interview, which must be administered by a trained clinician, requires 30 to 60 minutes to complete, whereas the self-report version is somewhat faster. Reliability and validity data for both the EDE and EDE-Q are excellent, although the EDE-Q may have greater sensitivity for binge-eating disorder. The EDE performs well in both the diagnosis and the detailed assessment of eating disorders in the research context. It also has the sensitivity to change required for use in clinical trials or monitoring of individual therapy. Even in the research setting, however, the EDE is fairly lengthy for repeated use, and the EDE-Q may be preferable for some purposes. Although the EDE is too lengthy for routine clinical practice, the EDE or EDE-Q might be helpful in providing a comprehensive assessment of a patient with a suspected eating disorder, particularly during an evaluation visit or on entry into an inpatient facility.

The Eating Disorders Assessment-5 (EDA-5). The Eating Disorders Assessment-5 (EDA-5), developed in 2014, is a semi-structured interview that was designed to assist clinicians in evaluating for DSM-5 Feeding and Eating Disorders in children and adults. The tool is administered by clinicians with expertise in the evaluation of eating disorders; there is also a computerized/internet version. The EDA-5 provides a series of probes to inquire about symptoms corresponding to DSM-5 criteria for each of the Feeding and Eating disorders. Clinicians ask follow-up questions as needed, and rate each criterion using all other available clinical information (e.g., behavioral observations, information from family, medical records, objective measures of height/weight, etc.). The EDA-5 employs an algorithm whereby subsequent questions are administered based on responses to previous questions, and thus the number of items administered varies across patients. The instrument takes roughly 20 to 30 minutes to complete. Although the measure appears promising for DSM-5 feeding and eating disorders, validity and reliability information remains limited given its recent release.

Neurocognitive Disorders

This subsection reviews measures of Major and Mild neurocognitive disorders, which primarily affect the older adults, where they are more commonly known as dementia and MCI; in younger patients, such as those with acquired cognitive disorders resulting from head injury or HIV, the term neurocognitive disorder is often preferred. A wide variety of measures are available, and the focus here on those commonly used among older patients. Most involve cognitive testing and provide objective, quantifiable data. However, scores vary by ability and by educational level in the general population, so these instruments are often more informative when the patient’s own baseline scores are known. Other measures focus on functional status, which can be assessed based on a comparison with a description of the subject’s baseline function; these types of measures generally require a knowledgeable informant and, thus, may be more cumbersome to administer but tend to be less subject to educational biases. A third type of measure focuses on the associated behavioral symptoms that are frequently seen in demented patients. Last, this subsection includes a measure of delirium, an acute or subacute confusional state resulting from a general medical condition.

Mini-Mental State Examination. The MMSE is a 30-point cognitive test developed in the mid-1970s to provide a bedside assessment of a broad array of cognitive function, including orientation, attention, memory, construction, and language. It can be administered in less than 10 minutes by a busy doctor or a technician and scored rapidly by hand. The MMSE has been extensively studied and shows excellent reliability when raters refer to consistent scoring rules. Validity appears good based on correlations with a wide variety of more comprehensive measures of mental functioning and clinicopathologic correlations. Although the MMSE is used commonly to screen for dementia, in both clinical practice and epidemiologic or clinical research, it is not optimal for this purpose, and even worse as a screen for MCI: it has limited memory items and no executive function items and thus tends to miss the areas most likely to be affected early in the course of disease. If the MMSE is used for screening, then a cutoff of 24 for identifying cases of dementia has been suggested, but it is probably more accurate to use age- and education-adjusted norms to interpret the results, and higher cutoffs are better for detecting MCI. For patients with extensive education, who may score 30 out of 30 despite clear evidence of functional decline, a more difficult cognitive test, full neuropsychological battery, or clinical interview about functional change may be required to detect dementia. The other principal use of the MMSE is in following the progression of dementia over time in the clinic or in clinical trials. As a rule of thumb, patients with mild dementia tend to score from 20 to 24, moderate from 11 to 19, and severe from 0 to 10. However, it should be noted that these figures do not take the educational differences noted above into account. In addition, the MMSE does not do as well tracking progression of dementia at later stages; scores of 10 or less are difficult to obtain, as many patients become untestable.

The Montreal Cognitive Assessment. The Montreal Cognitive Assessment (MoCA) is a brief, 30-point cognitive screening measure that was developed in the late 1990s to address many of the shortcomings of the MMSE, and to assist in detecting MCI and early Alzheimer dementia (AD) (Table 7.8–10). The MoCA evaluates a number of cognitive domains including memory (immediate and short delayed recall), attention and working memory, visuospatial abilities, executive functioning, language, and orientation. MoCA scores range from 0 to 30 (with higher scores indicating better functioning), and a cut-score of 26 has been suggested as differentiating normal from abnormal scores. It can be administered by a busy physician or technician in as little as 5 to 10 minutes. However, as of September 2019 the test developer now requires professionals to undergo formal training prior to administering the tool with patients. Initial validation research indicates that sensitivity and specificity of the MoCA in detecting patients with MCI and AD have generally been promising and superior to the MMSE, although research in other settings has been somewhat mixed. As noted above with the MMSE, the MoCA may provide for a useful bedside evaluation and/or briefer assessment of cognitive functioning in settings where more in-depth testing is challenging, although more comprehensive neuropsychological testing may ultimately be necessary in making a differential diagnosis and/or providing a more nuanced picture of someone’s level of functioning. This is particularly true in highly educated populations, where cognitive decline may be more difficult to detect due to ceiling effects in screening measures like the MMSE and MoCA.

Clinical Dementia Rating Scale. The Clinical Dementia Rating Scale (CDR) is a standardized staging system for dementia based on all available information about the patient. It was developed in 1992 and in 1993 was revised slightly in the context of a standard assessment protocol. Patients are rated in each of six domains (memory, orientation, judgment and problem solving, community affairs, home and hobbies, and personal care) on a scale from 0 to 3 (0 = no dementia, 0.5 = questionable dementia [approximately equivalent to MCI], 1 = mild dementia, 2 = moderate dementia, 3 = severe dementia), with detailed descriptions to anchor the ratings in each area. The ratings in each domain are typically combined into an overall CDR rating on the same scale following a weighting system that favors memory. However, they can also be summed to generate a CDR Sum of Boxes score. The staging system can be used on its own or based on the CDR protocol, a semi-structured interview with the patient and an informant, plus brief bedside cognitive testing. Ratings can be made relatively quickly by a clinician who is very familiar with the patient, but the full protocol requires 1 hour or more to administer. CDR ratings of 4 (profound dementia) and 5 (terminal dementia) are based on overall status. Whether based on the CDR protocol or on clinical experience with the patient, the CDR must be rated by a trained clinician. Additional training in the use of the scale and protocol are strongly recommended. The reported reliability of CDR scores based on the full protocol is high, but achieving this level of reliability requires extensive training. Validity of the CDR has also been shown to be high. A somewhat shorter interview and informant questionnaire are also available. Although the CDR *protocol* is clearly intended for research, the CDR *scale* is of potential use as a stage marker for clinical communication and charting decline over time. It is also helpful for understanding the dementia research literature, as the CDR and CDR—Sum of Boxes (SOB) are increasingly used as stage markers for clinical trials and other research. However, the CDR's lack of detail makes it relatively insensitive to change over short periods (the average annual decline is approximately one half-stage per year), and the CDR Sum of Boxes is only modestly better. In addition, the CDR was developed based on the typical course of Alzheimer disease, and tends to perform less well in patients with other dementing illnesses.

Neuropsychiatric Inventory. The Neuropsychiatric Inventory (NPI) was developed in the mid-1990s to assess a wide range of behavioral symptoms that are often seen in Alzheimer disease and other dementing disorders. The current version rates 12 areas: delusions, hallucinations, dysphoria, anxiety, agitation/aggression, euphoria, disinhibition, irritability/lability, apathy, aberrant motor behavior, nocturnal disturbances, appetite, and eating. The standard NPI is an interview with a caregiver or other informant that can be performed by a clinician or trained lay interviewer and requires 15 to 20 minutes to complete. There is also a nursing home interview version, the NPI-NH, and a self-report questionnaire, the NPI-Q. For each area, the NPI asks whether a symptom is present and, if so, assesses frequency, severity, and associated caregiver distress. The instrument has demonstrated reliability and validity and is useful to screen for problem behaviors in both clinical and research settings. Because of the detailed frequency and severity ratings, it is also useful to monitor change with treatment.

Confusion Assessment Method. The Confusion Assessment Method (CAM) was developed in 1990 as a standardized method for identifying delirium. It is typically administered by a clinical interviewer (or lay interviewer with specialized training), and takes roughly 5 to 10 minutes to complete. Full- and short-forms are also available. The CAM short-form specifically assesses for the presence/absence of the following in making a determination about possible delirium: (1) mental status altered from baseline (acute onset or fluctuating); (2) inattention; (3) disorganized thinking; and (4) altered level of consciousness. Delirium is identified when both conditions 1 and 2, and either 3 or 4 (or both) are met. The CAM long form assesses the same four domains above, as well as the following: (5) disorientation; (6) memory impairment; (7) perceptual disturbance; (8) psychomotor agitation and retardation; and (9) altered sleep–wake cycle. There has been a considerable amount of research on the CAM over the last few decades in support of its reliability and validity, and the tool has since been translated into 14 languages.

Personality Disorders and Personality Traits

Personality may be conceptualized categorically as personality disorders or dimensionally as personality traits, which may be viewed as normal or pathologic. The focus here is on personality disorders and the maladaptive traits generally viewed as their milder forms. Although the most recent DSM-5-TR retained the diagnostic system used in DSM-IV for diagnosing personality disorders, an alternative hybrid DSM-5-TR model for personality disorders is also included in Section III. The APA noted that it would include both options to ensure continuity with current and prior clinical and research practice, while also providing a structure for investigating a newer model designed to address many of the shortcomings in the current system. The DSM-5-TR continues to define 10 personality disorders in three clusters. Patients tend not to fall neatly into these personality categories; instead, most patients who meet criteria for one personality disorder also meet criteria for at least one other, particularly within the same cluster. This and other limitations in the validity of the constructs themselves make it difficult to achieve validity in personality measures. Personality measures include both interviews and self-report instruments. Self-report measures are appealing in that they require less time and may appear less threatening to the patient. Because many of the symptoms suggesting personality problems are socially undesirable and because patients' insight tends to be limited, clinician-administered instruments, which allow for probing and patient observation, may provide more accurate data.

Structured Clinical Interview for DSM Personality Disorders. The Structured Clinical Interview for DSM-5 Personality Disorders (SCID-5-PD) is the counterpart of the SCID for making DSM diagnoses of personality disorders. The initial version was developed for the DSM-III-R in the mid-1990s, and the current version makes diagnoses according to the DSM-5. The SCID-5-PD is organized by disorder and includes all ten DSM personality disorders, as well as Other Specified Personality Disorder. Although the DSM-5 retained the same classification system for diagnosing personality disorders as DSM-IV, the SCID-5-PD was updated to more optimally capture these diagnostic criteria and a dimensional scoring approach was also included—in keeping with important advances in field that have called into question categorical approaches to diagnosis. In addition to the primary interview structure, which includes core questions about each of the 10 personality disorders, there is also an optional SCID-5-SPQ that serves as a brief (20-minute) self-report screening tool that can be used to reduce the time of the SCID-5-PD interview. The SCID-5-PD must be administered by doctoral-level clinicians, and training is also required. A computerized administration and scoring program is available. Reliability is good for the presence or absence of any disorder but only fair for specific personality disorders; the reliability of dimensional assessment is somewhat better. Validity is somewhat harder to determine. Agreement with clinician assessment tends to be modest, but given the instrument's comprehensiveness and strict adherence to DSM criteria, the SCID-I5-PD may actually be more valid than clinician ratings. The SCID-II is most useful to provide a standardized, comprehensive assessment of personality disorders, whether in research, forensic, or clinical settings.

Personality Disorder Questionnaire. The Personality Disorder Questionnaire (PDQ) was developed in the late 1980s as a simple self-report questionnaire designed to provide categorical and dimensional assessment of DSM-III-R personality disorders and was subsequently revised for the DSM-IV (and retained by DSM-5) and renamed the PDQ-4. Another alternative version allows for ratings within the last few weeks and is designed to serve as a change measure. The PDQ-4 includes 85 yes–no items, designed primarily to assess the diagnostic criteria for DSM-IV/DSM-5 personality disorders. Within the 85 items, two validity scales are embedded to identify underreporting, lying, and inattention. There is also a brief clinician-administered Clinical Significance Scale to address the impact of any personality disorder identified by the self-report PDQ. The PDQ can provide categorical diagnoses, a scaled score for each, or an overall index of personality disturbance based on the sum of all of the diagnostic criteria. Overall scores range from 0 to 79; patients with personality disorders generally score above 30, psychotherapy outpatients without such disorders tend to score in the 20 to 30 range, and normal controls tend to score below 20. The PDQ can be completed in less than 30 minutes. Computerized administration and scoring are available. Reliability is fair to good for dimensional assessment and quite variable for categorical assessment, with good reliability for obsessive-compulsive and antisocial personality disorders and inadequate reliability for many disorders. Validity judged against semi-structured clinician-administered interviews is also variable. The PDQ, like other self-report instruments, tends to over-diagnose personality disorders, with many false positives and few false negatives. Its brevity, good sensitivity, and poor specificity make it most useful as a screening device, with patients screening positive being followed up with a detailed clinical evaluation or administration of a semi-structured interview.

The Personality Inventory for DSM-5 and Personality Inventory for DSM-5 Brief Form. The Personality Inventory for DSM-5 (PID-5) was developed in 2012 to measure the five higher-order domains (or dimensions) that are included in the alternative Section III of DSM-5, and have been shown to account for a significant amount of the variance observed across the personality disorders: Negative Affect, Detachment, Antagonism, Disinhibition, and Psychoticism. These five domains encompass twenty-five lower order "facets," which themselves represent different features of the higher-order construct. For example, the higher-order dimension of Negative Affect may include lower-order features of anxiety, depressivity, affective instability, and anhedonia. The PID-5 is a 220-item measure that yields scores at both the domain and facet levels, while the Personality Inventory for DSM-5 Brief Form (PID-5-BF) is a briefer 25-item measure designed to yield scores at the domain level only. Initial psychometric testing of these measures has been promising, and in many ways these tools reflect more recent conceptualizations of personality functioning—where the combination and severity of these traits are seen to have more predictive power than a simple criteria-based approach alone. Regardless, these instruments were published only in 2012, so further research is needed to better understand their contribution and clinical utility.

Childhood Disorders

A wide variety of instruments are available to assess mental disorders in children. Despite this rich array of instruments, however, the evaluation of children remains difficult for several reasons. First, the child psychiatric nosology is at an earlier stage of development, and construct validity is often problematic. Multiple changes in diagnostic criteria from DSM-III to DSM-III-R to DSM-IV to DSM-5 complicate the choice of measures. Second, because children change markedly with age, it is virtually impossible to design a measure that covers children of all ages. Last, because children, particularly young children, have limited ability to report their symptoms, other informants are necessary. This often creates problems because there are frequent disagreements among child, parent, and teacher reports of symptoms, and the optimal way to combine information is unclear.

Child Behavior Checklist. The Child Behavior Checklist (CBCL) is a family of self-rated instruments that survey a broad range of difficulties encountered in children from preschool through adolescence. One version of the CBCL, designed for completion by parents of children between 6 and 18 years of age, is shown in Table 7.8–11. Another version is available for parents of children between 1.5 and 5 years of age. The Youth Self-Report is completed by children between 11 and 18 years of age, and the Teacher Report Form is completed by teachers of school-age children. The scale includes not only problem behaviors, but also academic and social strengths. Each version includes approximately 100 items scored on a three-point Likert scale. Scoring can be done by hand or computer, and normative data are available for each of the three subscales: Problem behaviors, academic functioning, and adaptive behaviors. A computerized version is also available. The CBCL does not generate diagnoses but, instead, suggests cutoff scores for problems in the "clinical range." Parent, teacher, and child versions all show high reliability on the problem subscale, but the three informants frequently do not agree with one another. The CBCL may be useful in clinical settings as an adjunct to clinical evaluation, as it provides a good overall view of symptomatology and may also be used to track change over time. It is used frequently for similar purposes in research involving children and, thus, can be compared to clinical experience. The instrument does not, however, provide diagnostic information, and its length limits its efficiency for tracking purposes.

Diagnostic Interview Schedule for Children. The DISC was originally developed in the early 1990s as a fully structured diagnostic interview for making DSM-III diagnoses in children. It has since been revised for the DSM-III-R, DSM-IV, and more recently DSM-5. The current DISC-5 covers a broad range of DSM-5 diagnoses, both current and lifetime. It has nearly 3,000 questions but is structured with a series of stem questions that serve as gateways to each diagnostic area, with the remainder of each section skipped if the subject answers no. Subjects who enter each section have very few skips, so complete diagnostic and symptom scale information can be obtained. Child, parent, and teacher versions are available. Computer programs are available to implement diagnostic criteria and generate severity scales based on each version or to combine parent and child information. A typical DISC interview may take more than

1 hour for a child, plus an additional hour for a parent. However, because of the stem question structure, the actual time varies widely with the number of symptoms endorsed. The DISC was designed for lay interviewers. It is fairly complicated to administer, and formal training programs are highly recommended. Reliability of the DISC is only fair to good and generally better for the combined child and parent interview. Validity judged against a clinical interview by a child psychiatrist is also fair to good—better for some diagnoses and better for the combined interview. The DISC is well tolerated by parents and children and can be used to supplement a clinical interview to ensure comprehensive diagnostic coverage. Because of its inflexibility, some clinicians find it uncomfortable to use, and its length makes it less than optimal for use in clinical practice. However, it is used frequently in a variety of research settings.

2. Does your child receive special education or remedial services or attend a special class or special school?

☐ No ☐ Yes — kind of services, class, or school:

3. Has your child repeated any grades? ☐ No ☐ Yes — grades and reasons:

4. Has your child had any academic or other problems in school? ☐ No ☐ Yes — please describe:

When did these problems start?

Have these problems ended? ☐ No ☐ Yes — when?

Does your child have any illness or disability (either physical or mental)? ☐ No ☐ Yes — please describe:

What concerns you most about your child?

Please describe the best things about your child.

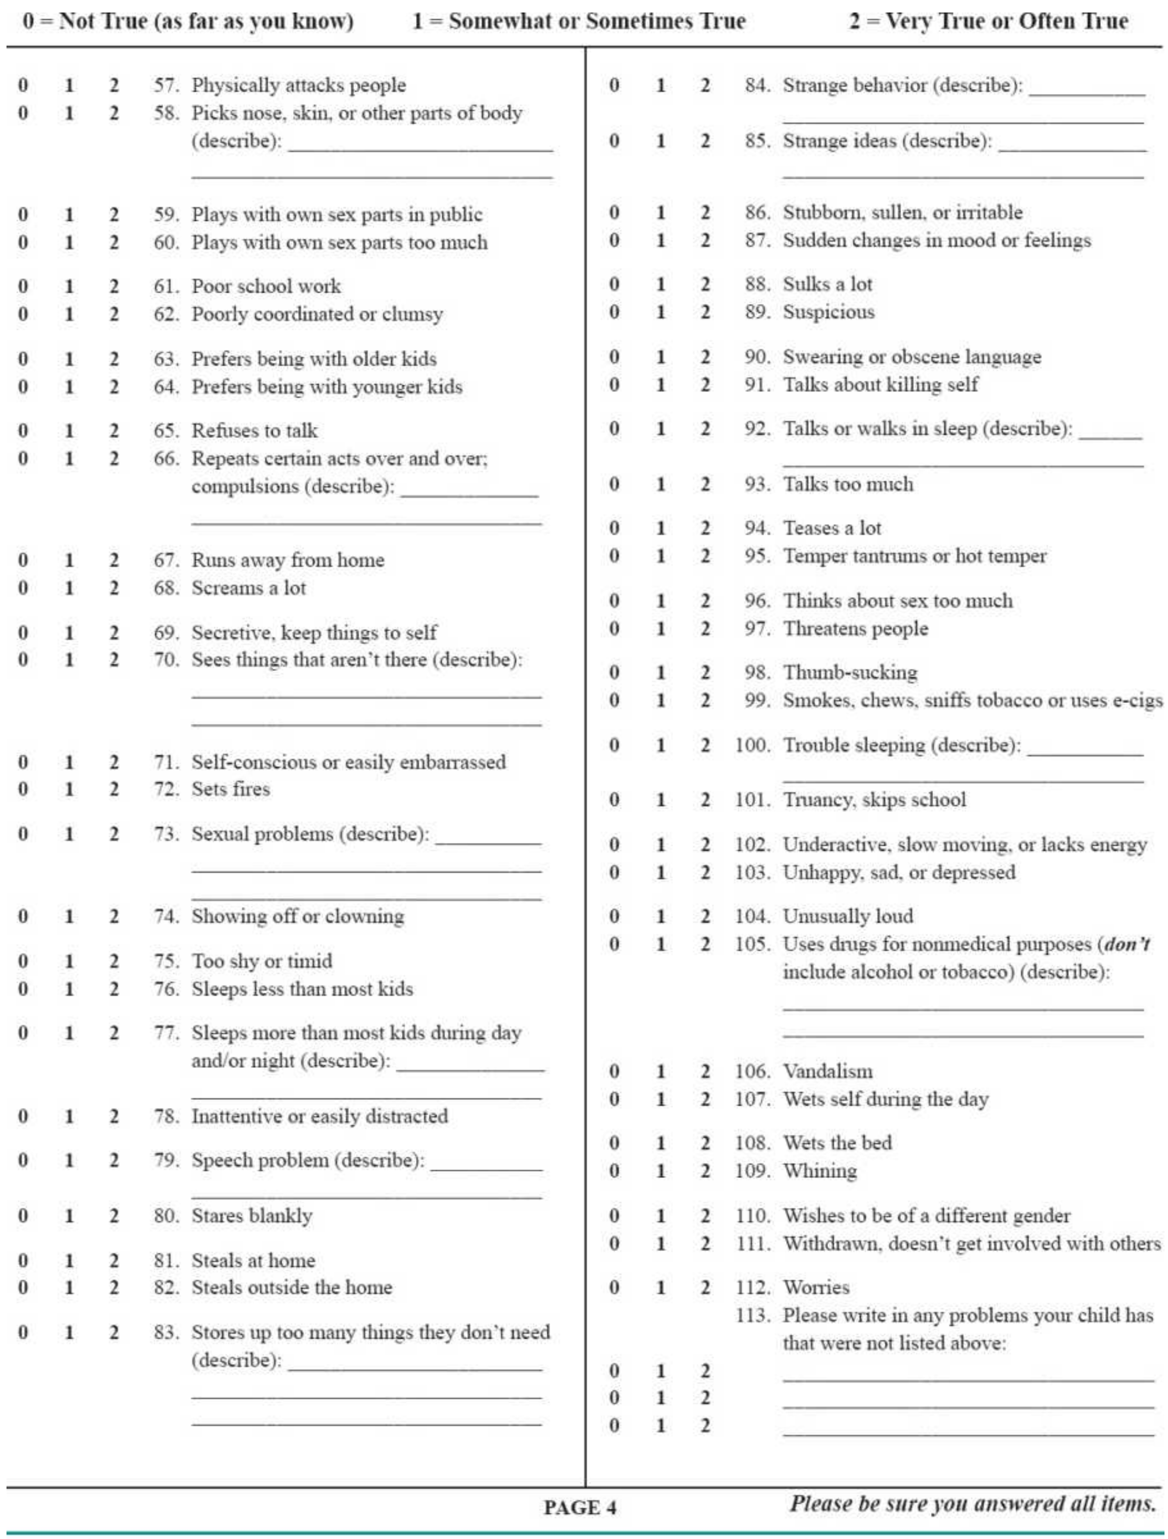
Please be sure you answered all items.

Below is a list of items that describe children and youths. For each item that describes your child ***now or within the past 6 months***, please circle the *2* if the item is ***very true or often true*** of your child. Circle the *1* if the item is ***somewhat or sometimes true*** of your child. If the item is ***not true*** of your child, circle the ***0***. Please answer all items as well as you can, even if some do not seem to apply to your child.

0 = Not True (as far as you know) **1 = Somewhat or Sometimes True** **2 = Very True or Often True**

0	1	2	1. Acts too young for age
0	1	2	2. Drinks alcohol without parents' approval (describe): ________________ ________________
0	1	2	3. Argues a lot
0	1	2	4. Fails to finish things they start
0	1	2	5. There is very little they enjoy
0	1	2	6. Bowel movements outside toilet
0	1	2	7. Bragging, boasting
0	1	2	8. Can't concentrate, can't pay attention for long
0	1	2	9. Can't get mind off certain thoughts; obsessions (describe): ________________ ________________
0	1	2	10. Can't sit still, restless, or hyperactive
0	1	2	11. Clings to adults or too dependent
0	1	2	12. Complains of loneliness
0	1	2	13. Confused or seems to be in a fog
0	1	2	14. Cries a lot
0	1	2	15. Cruel to animals
0	1	2	16. Cruelty, bullying, or meanness to others
0	1	2	17. Daydreams or gets lost in thoughts
0	1	2	18. Deliberately harms self or attempts suicide
0	1	2	19. Demands a lot of attention
0	1	2	20. Destroys own things
0	1	2	21. Destroys things belonging to family or others
0	1	2	22. Disobedient at home
0	1	2	23. Disobedient at school
0	1	2	24. Doesn't eat well
0	1	2	25. Doesn't get along with other kids
0	1	2	26. Doesn't seem to feel guilty after misbehaving
0	1	2	27. Easily jealous
0	1	2	28. Breaks rules at home, school, or elsewhere
0	1	2	29. Fears certain animals, situations, or places, other than school (describe): ________________ ________________
0	1	2	30. Fears going to school
0	1	2	31. Fears they might think or do something bad
0	1	2	32. Feels they have to be perfect
0	1	2	33. Feels or complains that no one loves them
0	1	2	34. Feels others are out to get them
0	1	2	35. Feels worthless or inferior
0	1	2	36. Gets hurt a lot, accident-prone
0	1	2	37. Gets in many fights
0	1	2	38. Gets teased a lot
0	1	2	39. Hangs around with others who get in trouble
0	1	2	40. Hears sounds or voices that aren't there (describe): ________________ ________________
0	1	2	41. Impulsive or acts without thinking
0	1	2	42. Would rather be alone than with others
0	1	2	43. Lying or cheating
0	1	2	44. Bites fingernails
0	1	2	45. Nervous, highstrung, or tense
0	1	2	46. Nervous movements or twitching (describe): ________________ ________________
0	1	2	47. Nightmares
0	1	2	48. Not liked by other kids
0	1	2	49. Constipated, doesn't move bowels
0	1	2	50. Too fearful or anxious
0	1	2	51. Feels dizzy or lightheaded
0	1	2	52. Feels too guilty
0	1	2	53. Overeating
0	1	2	54. Overtired without good reason
0	1	2	55. Overweight
			56. Physical problems ***without known medical cause:***
0	1	2	a. Aches or pains (***not*** stomach or headaches)
0	1	2	b. Headaches
0	1	2	c. Nausea, feels sick
0	1	2	d. Problems with eyes (***not*** if corrected by glasses) (describe): ________________
0	1	2	e. Rashes or other skin problems
0	1	2	f. Stomachaches
0	1	2	g. Vomiting, throwing up
0	1	2	h. Other (describe): ________________ ________________

Please be sure you answered all items. Then see other side.



0 = Not True (as far as you know) 1 = Somewhat or Sometimes True 2 = Very True or Often True

0 1 2 57. Physically attacks people
0 1 2 58. Picks nose, skin, or other parts of body (describe): ____________________

0 1 2 59. Plays with own sex parts in public
0 1 2 60. Plays with own sex parts too much

0 1 2 61. Poor school work
0 1 2 62. Poorly coordinated or clumsy

0 1 2 63. Prefers being with older kids
0 1 2 64. Prefers being with younger kids

0 1 2 65. Refuses to talk
0 1 2 66. Repeats certain acts over and over; compulsions (describe): ____________________

0 1 2 67. Runs away from home
0 1 2 68. Screams a lot

0 1 2 69. Secretive, keep things to self
0 1 2 70. Sees things that aren't there (describe): ____________________

0 1 2 71. Self-conscious or easily embarrassed
0 1 2 72. Sets fires

0 1 2 73. Sexual problems (describe): ____________________

0 1 2 74. Showing off or clowning

0 1 2 75. Too shy or timid
0 1 2 76. Sleeps less than most kids

0 1 2 77. Sleeps more than most kids during day and/or night (describe): ____________________

0 1 2 78. Inattentive or easily distracted

0 1 2 79. Speech problem (describe): ____________________

0 1 2 80. Stares blankly

0 1 2 81. Steals at home
0 1 2 82. Steals outside the home

0 1 2 83. Stores up too many things they don't need (describe): ____________________

0 1 2 84. Strange behavior (describe): ____________________

0 1 2 85. Strange ideas (describe): ____________________

0 1 2 86. Stubborn, sullen, or irritable
0 1 2 87. Sudden changes in mood or feelings

0 1 2 88. Sulks a lot
0 1 2 89. Suspicious

0 1 2 90. Swearing or obscene language
0 1 2 91. Talks about killing self

0 1 2 92. Talks or walks in sleep (describe): ____________________

0 1 2 93. Talks too much

0 1 2 94. Teases a lot
0 1 2 95. Temper tantrums or hot temper

0 1 2 96. Thinks about sex too much
0 1 2 97. Threatens people

0 1 2 98. Thumb-sucking
0 1 2 99. Smokes, chews, sniffs tobacco or uses e-cigs

0 1 2 100. Trouble sleeping (describe): ____________________

0 1 2 101. Truancy, skips school

0 1 2 102. Underactive, slow moving, or lacks energy
0 1 2 103. Unhappy, sad, or depressed

0 1 2 104. Unusually loud
0 1 2 105. Uses drugs for nonmedical purposes (*don't* include alcohol or tobacco) (describe): ____________________

0 1 2 106. Vandalism
0 1 2 107. Wets self during the day

0 1 2 108. Wets the bed
0 1 2 109. Whining

0 1 2 110. Wishes to be of a different gender
0 1 2 111. Withdrawn, doesn't get involved with others

0 1 2 112. Worries
113. Please write in any problems your child has that were not listed above:

Conners Rating Scales. The Conners Rating Scales are a family of instruments designed to measure a range of childhood and adolescent psychopathology but are most commonly used in the assessment of ADHD. There are teacher, parent, and self-report (for adolescents) versions and both short (as few as 10 items) and long (as many as 80 items, with multiple subscales) forms. Extensive normative data drawn from an ethnically diverse population are available for each sex across a broad age range. Even the longer forms can be completed in 15 to 20 minutes, and scoring can be accomplished rapidly. Training for raters is not required. Reliability data are excellent for the Conners Rating Scales. However, teacher and parent versions tend to show poor agreement. Validity data suggest that the Conners Rating Scales are excellent at discriminating between ADHD patients and normal controls. It has more difficulty separating ADHD from other disruptive behavioral disorders, such as conduct disorder, but this may be partly related to the genuine clinical difficulties separating these syndromes. Newer versions of the Conners Rating Scales have been developed that aim to improve these discriminations but have not yet been subjected to extensive testing. The principal uses of the Conners Rating Scales are in screening for ADHD in school or clinic populations and following changes in symptom severity over time; sensitivity to change in response to specific therapies has been demonstrated for most versions of the Conners Rating Scales.

Autism Diagnostic Interview—Revised. The Autism Diagnostic Interview (ADI) was developed in 1989 as a clinical assessment of autism and related disorders. The revised ADI-R was developed in 2003 with an aim to providing a shorter instrument with better ability to discriminate autism from other developmental disorders. The instrument has 93 items, is designed for individuals with a mental age greater than 18 months, and covers 3 broad areas, consistent with the DSM-5-TR criteria for autism: language and communication; reciprocal social interactions; and restricted, repetitive, and stereotyped behaviors and interests. There are three versions: one for lifetime diagnosis, one for current diagnosis, and one for patients under 4 focused on considering an initial diagnosis of autism. It must be administered by a clinician trained in its use and takes about 90 minutes to complete. When clinicians are properly trained, it has good to excellent reliability and validity but performs poorly in the setting of severe developmental disabilities. It is generally intended for the research setting, when a thorough assessment of autism is required but may have use in clinical practice as well.

7.9 Electronic Media in Psychiatry

ZEBULON TAINTOR, M.D.

This section is shaped by two forces: technology and the coronavirus (COVID-19) pandemic. Technology has developed in many directions and penetrated almost everywhere, offering diverse, unexpected choices. Concurrently, the pandemic has limited our choices, forcing us to rely on technology, ranging from mRNA to communication and its pitfalls. This subsection considers the use of remote communications with patients and among people and developments in health information technology because of the applications of microprocessors in both areas.

DEFINITIONS AND LEGISLATIVE HISTORY

The prefix "*tele*" denoting transmission over a distance, is used to form *telegraph*, involving the transmission of text, now involving digital code, telephone, which adds sounds, and television, which adds images. *Telemedicine* and *telepsychiatry* are, respectively, the practice of medicine and the medical specialty of psychiatry using television. The prefix "*video*" denotes images, increasingly transmitted as still or moving. *Virtual reality* surrounds a person (using wraparound goggles or a helmet) with a simulated environment. *Holographic projections* intrude three-dimensional images into the real environment and, like virtual reality, can be used in therapy. *E-therapy* is therapy done by electronic communication, often with attachments. Apps are computer programs that perform specific tasks (as contrasted with operating systems in which apps are housed). Most are developed for electronic devices, increasingly connected handheld computers (*smartphones*) that can handle text, sound, and video. *Interactive* apps use two-way communication between user and program. *Online* means connected to the World Wide Web (internet), providing immediate availability for a response, while *asynchronous* connections involve delays between responses. *Unmet online therapy* denotes therapy in which therapist and patient have not met. *Face-to-face* (often abbreviated to *F2F*) therapy involves meeting in person, not necessarily touching, but being able to do so without electronics involved. *Hybrid therapy* combines any of the above, usually with F2F and something else.

Other definitions have emerged with electronic storage and retrieval of medical records. The *Health Information Portability and Accountability Act (HIPAA)*, amended several times since its passage in 1996, defines most terms for electronic records in health care. *Protected Health Information (PHI)* is any health information linked to a specific individual. Privacy rights guarantee that PHI is under a person's control and may not be released without patient consent except as required by law, for example, suspected child abuse. The Center for Medical Services (CMS) (update July 2, 2021) defines HIPAA-*covered entities* to include health plans, clearinghouses, and certain health care providers as follows: *Health Plans:* health insurance companies, HMOs, or health maintenance organizations, employer-sponsored health plans, Government programs that pay for health care, like Medicare, Medicaid, and military and veterans' health programs; *Clearinghouses:* organizations that process nonstandard health information to conform to standards for data content or format, or vice versa, on behalf of other organizations; *Providers:* those who submit HIPAA transactions, like claims, **electronically** are covered, including, but not limited to doctors, clinics, psychologists, dentists, chiropractors, nursing homes, and pharmacies. *Business Associates* are engaged by a covered entity to help carry out its health care activities and functions. There must be a written business associate contract or another arrangement that establishes specifically what the business associate has been engaged to do and requires the business associate to comply with HIPAA.

Examples of Business Associates include the following:

- A third-party administrator that assists a health plan with claims processing
- A consultant that performs utilization reviews for a hospital
- A health care clearinghouse that translates a claim from a nonstandard format into a standard transaction on behalf of a health care provider and forwards the processed transaction to a payer
- An independent medical transcriptionist that provides transcription services to a physician
- Also, a covered health care provider, health plan, or health care clearinghouse can be a business associate of another covered entity

Insurance reimbursement for services provided obtains patient consent for sharing PHI, shared as needed among covered entities and business associates.

Entities not directly linked to reimbursement (e.g., a *Regional Health Information Organization [RHIO]* set up to promote communication among clinicians) require consent according to state laws governing privacy that give patients the right to dictate with whom or what their PHI may be shared.

Although the American Psychiatric Association and other privacy advocates press for *granularity* (enabling the item-by-item retention or release of any item of PHI to any specific person or agency, e.g., deciding one hospital but not another in an RHIO has access to one's PHI, or that pregnancy data be withheld), consent often is a blanket opt in or opt out.

Self-pay patients have complete control over their PHI. HIPAA provides blanket privacy protection for *psychotherapy notes.* The PHI of individuals who receive drug and alcohol abuse treatment in federally funded programs is subject to additional privacy protections under 42 USC § 290dd-2 and 42 CFR § 2.11 (Part 2). HIPAA does not state who owns PHI, only that it must be protected. Each covered entity must have a privacy officer, have written privacy policies and practices available on request, and keep track of PHI disclosures. Individuals may complain to clearinghouses: organizations of the Department of Health and Human Services (HHS) of suspected privacy violations.

The HITECH (Health Information Technology for Economic and Clinical Health) Act of 2009 was an economic stimulus for electronic health records (EHRs) (only 10% of hospitals had them), but it strengthened and sharpened HIPAA. The HITECH Act contains four subtitles (A to D). Subtitle A concerns the promotion of health information technology and is split into two parts. Part 1 is concerned with improving health care quality, safety, and efficiency. Part 2 is concerned with applying and using health information technology standards and reports. Subtitle B covers testing of health information technology, Subtitle C covers grants and loans funding, and Subtitle D covers privacy and security of electronic health information. Subtitle D is also split into two parts. Part 1 is concerned with improving privacy and security of Health information technology (HIT) and PHI, and part 2 covers the relationship between the HITECH Act and other laws. Compliance with the requirements of the HITECH Act became enforceable on November 30, 2009, 12 months following the Act being signed into law. The HITECH requirements were incorporated into HIPAA in the Final Omnibus Rule, which brought HIPAA and HITECH together into the same legislation. The HIPAA Omnibus Final Rule was published on January 25, 2013, and had a compliance date of September 23, 2013.

The HHS was given over $25 billion to achieve its goals. The HHS used some of that budget to fund the *Meaningful Use* program, incentivizing care providers to adopt certified EHRs by offering monetary incentives. Certified EHRs have been certified as meeting defined standards by an authorized testing and certification body. Certified EHRs had to be used in a meaningful way, such as for issuing electronic prescriptions and exchanging electronic health information to improve the quality of care. The financial incentives were significant and increased with each year of the program, and new requirements were introduced at each of the three stages of the Meaningful Use program. The failure to meet the requirements of each stage resulted in a financial penalty (reduction of reimbursements for Medicare and Medicaid). In order to qualify for federal funds, care providers not only had to adopt EHRs but also demonstrate meaningful use of certified EHRs. They had to demonstrate that they had achieved the minimum core objectives in each stage in addition to a set number of menu objectives. It was also necessary to demonstrate compliance with the HIPAA Security and Privacy Rules by conducting risk assessments. Loss of protection for PHI is termed a *data breach*, **all of which** now must be reported to HHS. All reported breaches are investigated, and fines may be imposed from $100 to $50,000/violation (maximum $1.5 million/year). Breaches involving more than 500 people must be reported as soon as known, with penalties of more than a 60-day delay. These are listed (https://ocrportal.hhs.gov/ocr/breach/breach_report.jsf), which showed 842 between October 17, 2019, and October 5, 2021.

The movement to EHRs resulted in the marketing of many systems, which differ in the type of data collected and the software design. Many were clinical add-ons to billing/administrative systems (*Practice Management Software [PMS]*). Efforts at quality control resulted in the Certification Commission for Health Information Technology (CCHIT), founded in 2004. A determinedly collegial process involving many stakeholders in many committees, workgroups set standards for privacy and compliance, security networking (connecting electronic devices within an organization), interoperability (enabling uploading PHI to, and use via, other electronic devices), and the *Continuity of Care Health Record (CCHR)*, what one physician can expect another to tell about a patient. It agreed on sets of items required in various general and specialty-specific EHRs. For several years, CCHIT was to EHRs what the Joint Commission on the Accreditation of Health Care Organizations (JCAHO) is to hospitals and clinics. However, protests about the fees charged for what was seen as too lugubrious a process for certifications resulted in looser standards and competing certifying organizations. The Office of the National Coordinator authorized six (now four) authorized and testing bodies for EHRs and EHR modules (https://www.healthit.gov/topic/certification-ehrs/certification-process), currently 915, mostly modules (https://chpl.healthit.gov/#/search). Users bewail the apparent lack of usability as a certification criterion, despite lip service to the same.

Under Administrative Simplification (a title seen by many as ironic), HHS set documentation standards and rules for Privacy Security, Transactions, and Code Sets (with CPT codes set by the American Medical Association). The CMS, part of HHS, sets documentation standards for Medicare and, somewhat, for Medicaid. As these were seen as burdensome, the Office of the National Coordinator for Health Information Technology (ONCHIT) proclaimed in 2017 a priority of “Patients Over Paperwork.”

HIPAA and HITECH strengthened patient rights to their medical records. Some EHRs spin-off *Personal Health Records (PHRs)* for their patients. Others allow access to lab data, prescription records, visit summaries, etc. The movement is to share more data with patients, especially as they pick up errors. On April 5, 2021, federal rules implemented the bipartisan 21st Century Cures Act Open Notes, specifying that eight types of clinical notes are among electronic information that must not be blocked and must be made available free of charge to patients. To meet the interests of some patients, the rules allow specified exceptions (www.opennotes.org/onc-federal-rule). While simply opening the entire EHR is temptingly little work, some problems arise, such as reading a pathology report of metastatic cancer before one's physician has seen it or feeling hurt or insulted (https://www.nytimes.com/2021/09/30/well/live/medical-records-misunderstanding.html), so extra work is needed to screen the notes patients may see.

COMMUNICATION EVOLUTION

Written Words: From Letter Writing to Instant Messaging

An email basically is a letter, the most ancient form of communication across distance. People use letters to develop and give a particular form to a relationship. Various published correspondences often include the writers' agreement that the letters were more critical than actual meetings. Many examples show the process of psychotherapy in traditional letter writing. The first "email" device was the telegraph, first used between cities in 1844. Telegraphic style is usually preferred over formalities in email and texting, especially for asynchronous communication of attachments such as test results or directions. As cost is insignificant, use has increased exponentially, as recommended in 2001 by the Institute of Medicine's Committee on Quality of Health Care in America: Crossing the Quality Chasm: A New Health Care System for the 21st Century. Almost all email is retrievable and discoverable in litigation; clinicians should anticipate that emails may be regarded as part of the patient record.

Websites offering information, especially with a marketing component, often encourage emails. In addition, professional and self-help organizations have developed apps for patients to use as needed, for example, coping with anxiety, suicidal thoughts, urges to drink, or detecting depression.

Spoken Words: Telephone

Telephone calls have been used to help people feel better since the invention of the telephone in 1885. They are immediate (if answered, which is less frequent as Robo and other unwanted calls increase) and can convey nonverbal data through tone of voice, pauses, speed and rhythm of speech, and inflection. When costs were charged by time and distance, calls were brief, but now unlimited calling easily accommodates therapy sessions. In addition, while analog calls were not retrievable unless recorded, digital calls can be retrieved and recreated, although with varying degrees of difficulty.

Crisis hotlines are widely used for emergencies and are accepted as a necessary component of full service. There is extensive experience with telephone therapy in suicide prevention centers and other hotlines. Hotlines are growing to handle specific problems, such as urges to be violent. Answerers are always available. Caller and answerer have a cold start, not having talked previously or knowing anything about one another. Listening to call recordings leaves little doubt that the services provide meaningful help. However, suicide rates are not lowered significantly. It is assumed that the most seriously suicidal kill themselves rather than call. In general, callers use hotlines once or twice and are encouraged to go to services where they are seen and helped but use crisis hotlines and emergency rooms for months or years. Usually, the ongoing therapy is recognized, and a treatment plan is generated.

The use of the telephone to transmit images became widely available in 1964 to 1966 with the advent of Xerox's facsimile machines, which added images to long-distance relationships. Videophones initially were unpopular; the video function is now part of every smartphone but infrequently used by those concerned about how they appear. Smartphone video showing what someone else is doing is very frequent, while showing oneself is much less so, especially in conversation. People in the same room who could talk directly to each other sometimes text back and forth.

Spoken Word Recording

Both patients and therapists have recorded psychotherapy sessions since audiotape became available in the 1940s, especially as recording device storage and playback became more accessible and less expensive. State laws vary as to what permission must be obtained from the other party(ies) in a conversation before recording by telephone or in person, but therapists typically recognize that trust is paramount and get specific permission. Both patients and therapists use recordings between sessions to enhance efficacy in focusing on issues, interpretations, and what is happening otherwise.

Images: Television

Although television was invented before World War II, its use in therapy awaited recording media, initially videotape. Milton Berger demonstrated the use of videotaping group and other therapy sessions to help patients see themselves as others saw them, particularly how their body language conveyed unintended messages. As with audio recordings, a chance to step back into an observer role offers fresh insights, enhanced with facial expressions and body language. Televised sessions with patients are commonly used in teaching, available as DVDs, flash memory sticks, and storage on the internet.

Smartphones

The development of the smartphone, starting in 2000 as personal digital assistants (PDAs) added cellular telephony, combining mobile telephone and computing functions into one unit. The smartphone is truly revolutionary in many ways, potentially bringing every smartphone user in the world into contact with the internet and each other. Its many innovations included the primacy of a person’s finger as the input device. Use has extended to more than 3 billion individual users worldwide, likely growing several hundred million more in the next few years. All components have been improved, and the 5G network promises faster speeds. Smartphones have been likened to prosthetic brains with enhanced memories, as data can be retrieved easily from multiple sources. They enable a wide array of activities, almost immediately and readily available.

Accidents have increased as people on their phones do not see where they are going. Handheld phones are prohibited for drivers, but walking accidents have increased. Beneficial and detrimental effects on mental health have been reported, with excessive use seen as dependency and addiction, despite the lack of diagnostic criteria distinguishing between use and abuse, as is also the case for internet use (see below). Young people are seen as particularly vulnerable, and guidelines for use by children and families have been developed, including those from the American Academy of Pediatrics. Concerns about the device itself have centered on screen time, microwave proximity and duration, and sleep. As time spent looking at and manipulating a screen is time that could be spent otherwise, consequences stem from whatever activity is missed, such as work, education, or face-to-face socialization. Sleep consequences ensue from staying up with backlit blue light devices, somewhat ameliorated by programs that change screen color to warmer hues. Possible effects of microwave radiation, other than the 2011 report of increased activity in brain regions near smartphones, have not been shown, although investigations continue.

"There's an app for that" hints at the many millions of apps that have been developed. Notable worldwide, as of August 2021, are Instagram (photo sharing) with more than a billion (500+ million daily) users, WhatsApp (messaging, including video calls) with more than 2 billion monthly users generating more than 100 billion messages daily, and their owner, Facebook (2.85 billion monthly users). Tracking the number of downloads from app stores (e.g., Instagram, more than 6 billion) no longer matters as smartphones are increasingly sold with these apps already installed (e.g., almost all smartphones in Brazil). YouTube (videos, mostly noninteractive) is owned by Google and has about 2 billion monthly users. Specific apps (e.g., detecting depression by sensing cell phone movement) have small user bases and struggle to become known. Categories of mental health apps include programs for learning coping skills, therapy, stress relief, meditation, fun, depression, Black, indigenous [and] people of color (BIPOC), bipolar disorder, symptom tracking, attention deficit hyperactivity disorder (ADHD), and post-traumatic stress disorder (PTSD). Many apps have been developed by treatment systems, such as the Veterans Administration in the United States (https://www.va.gov/WHOLEHEALTH/veteran-resources/MobileApps-OnlineTools.asp), which also offers online tools such as podcasts, and the National Health System in the United Kingdom (https://www.nhs.uk/apps-library), especially for substance abuse and smoking cessation. The American Psychiatric Association and other professional groups have developed standards for evaluating apps and promoting user reviews.

While the efficacy of some apps has been established, most mental health apps (estimated total in October 2021: between 10,000 and 20,000) have been marketed without supporting data, resting on face value, and anecdotal evidence. Driving factors of 24/7 availability, low cost, and improvement with monitoring and process (rather than outcome) fuel more and more apps. Developers of medical and mental health apps often are frustrated by low uptake and use, envying apps that suddenly become widely used, for example, Tok-tok (Doujin in China) that, in 4 years, had 2 billion downloads worldwide (315 million as TikTok) and a third of social media users, a haven for short, fun videos. Harmful effects of some medical/mental health apps are not studied but occasionally spotted, for example, a suicide prevention app that was reported to increase suicidal thinking.

Telemedicine/Telepsychiatry

The first recorded use of telemedicine was in 1906 (ECG recordings by telephone). Digital images are routinely transmitted anywhere by radiologists. Telemedicine has been used for specialty consultations for decades. The costs for equipment and transmission became negligible as Zoom, GoToWebinAir, Cisco Webex, and other videoconferencing platforms offered free time. Increasing use requires payment, especially for HIPAA-compatible platforms. The COVID-19 pandemic severely limited in-person medical visits, so the use of videoconferencing skyrocketed. Telehealth claim lines rose 2,817% from December 2019 to December 2020, according to a March 2021 report that revealed how the COVID-19 pandemic has changed how health care is delivered and consumed. Compared to the same month in 2019, the volume of telehealth claim lines rose from 0.22% to 6.5%. Multiple policies and procedures were suspended, including medical licensing and liability laws, varying by state. The CMS provided federal waivers for Medicare and Medicaid, generally adopted by health insured. As the pandemic emergency wanes, some policy suspensions are being allowed to expire or are being reinstituted. At the same time, some changes may become permanent, for example, moving toward medical licensure across states or telemedical licenses that are separate from being physically present to see patients within a state. Florida now provides such a telemedical license. Inevitably, some data are lost off camera, and production values often are inconsistent, with too little attention to light, sound, or image centering. Data reduction is less of an issue for radiology, pathology, and, to a lesser extent, dermatology.

The first recorded use of telepsychiatry was in 1957. Telepsychiatry has benefitted by being seen as part of telemedicine, with established policies and procedures. Psychiatrists have been pleasantly surprised by most patients readily accepting telepsychiatry, especially happy with more scheduling flexibility and no travel time. The American Psychiatric Association offers a helpful toolkit (https://www.psychiatry.org/psychiatrists/practice/telepsychiatry/toolkit/) and collaborated in 2018 with the American Telehealth Association to offer Best Practices in Videoconferencing-Based Telemental Health (available at https://www.psychiatry.org/psychiatrists/practice/telepsychiatry/toolkit/best-practices)

Remote Monitoring. Patients with chronic illnesses treated according to significant biomarkers such as blood sugar for diabetes or blood pressure for hypertension are easily monitored either by harvesting the readings they take on themselves or through body-attached sensors that feed directly into their caretakers' inboxes.

> *In behavioral care, remote patient monitoring devices can help monitor sleep, diet, exercise, mood, and more…the government has been very willing to support and encourage increased utilization alongside telehealth. The efficacy of such tools is so high that Medicare has reimbursed for an increasing number of new RPM-related CPT codes for the last several years.* (With permission from Maheu MM. What is remote patient monitoring? Telehealth News, July 23, 2021. Available at: https://blog.telehealth.org/remote-patient-monitoring-2/)

Pending legislation would increase support. Companies offer remote vital signs and other monitoring during and between sessions and integration into the EHR. Biofeedback and neurofeedback remote monitoring has been reported for several problems with significant biomarkers, for example, anger management.

Reimbursement. Telemedicine reimbursement began in 1999 via Medicare. Coverage was expanded with the Telehealth and Improvement and Modernization Act of 2002. Some changes included the requirement that the "physician or provider" at a distant site be paid the same (consistent with parity laws) as if the services were provided face to face, the elimination of fee sharing, and the expansion of Current Procedural Terminology (CPT) codes eligible for telepsychiatry reimbursement. The

American Telemedicine Association, founded in 1993 (www.americantelemed.org), offers institutional memberships (currently about 400). It refers individual practitioners wishing to start using telemedicine to the National Consortium of Telehealth Resource Centers (12 regional, 2 national, https://telehealthresourcecenter.org/), funded by the Health Resources and Services Administration of HHS to increase rural health services. The American Medical Association, the American Psychiatric Association, and other medical organizations provide toolkits and other assistance to practitioners, while their committees promote the use and favorable policies.

Many studies have shown telepsychiatry equal to in-person visits for efficacy, quality of care, and patient satisfaction. Findings are robust across multiple patient groups and settings while lowering cost and increasing access and convenience. Prior to the pandemic, reimbursement claims typically fell short of budgeted amounts for Medicare and Medicaid, set to encourage use. Telemedicine had ups (especially favorable studies) and downs. In 2015, both Texas and Maryland significantly restricted telemedicine. The Association of Telehealth Service Providers and the Telemedicine Information Exchange shut down. Telemedicine showed some growth in the private sector, but the pandemic brought about exponential growth. Suddenly, there was no choice but to add telemedicine to a comfortable in-person practice. That practice had been locked down. Telemedicine was the only thing to do.

With the pandemic, use skyrocketed (85% to 90% practicing some form of electronic communication with their patients (36% of all patients) as of October 2021, and receiving payments is less of a problem than usual, especially as insurers were not having to pay for many elective procedures that were not being done.

Highly competent enthusiasts did many positive studies. However, practical experience with Zoom fatigue or the limitations of online schooling has resulted in a consensus that televisits often leave something to be desired. They seem to be less helpful and definitive than in-person visits, so hybrid models alternating the two have developed.

Government Support. Successive administrations have supported more access to health and the internet, especially in rural areas. Federal support began in 966 with $42 million from the National Library of Medicine for telemedicine projects. Funding increased fitfully over the years. The 2018 Farm Bill, passed December 12, 2018, included a grant program for distance learning and telemedicine (a 20% set aside whatever rural hospital funding was to be done) and $82 million/year for 2019 through 2023. With the pandemic, the Coronavirus Aid, Relief, and Economic Security (CARES) Act became law on March 20, 2020, establishing the Federal Communications Commission (FCC) COVID-19 Telehealth Program with initial funding of $200 million and additional funding for broadband initiatives in rural and low-income areas. The Consolidated Appropriations Act of 2021, passed December 21, 2020, added $250 million (for providers) to the FCC program, $3.2 billion to ensure that low-income consumers can access internet services at home. In addition, eligible telehealth individuals under Medicare can utilize telehealth to diagnose, treat, or evaluate mental health disorders without geographic restrictions. This new rule will become permanent after the Public Health Emergency ends. This new law also permits beneficiaries to receive telehealth services from their home for mental health diagnosis, treatment, or evaluation (in addition to substance use disorder treatment, which was previously allowed). The new law will apply to most telemental health services, including counseling, psychotherapy, and psychiatric evaluations.

There are critical stipulations regarding the scope of eligible telemental health services. Specifically, eligible patients must have an existing in-person relationship with a provider, as defined by at least one in-person visit within 6 months prior to the telehealth encounter and subsequent periods as determined by the Secretary. However, as written, the bill's language appears to require the in-person visit regardless of where the patient is located (e.g., home, clinic, doctor's office) if that location is newly eligible under the provision (e.g., a doctor's office in an urban area). This in-person requirement would not apply to any eligible location under the previous rules (e.g., eligible originating sites in rural areas).

Some states and some localities appropriated additional amounts to enhance telemedical services.

Licensure Issues. If the patients and physician are in the same state, the state medical license provides the practice framework, but being in different states has led to alternate licenses. The Commonwealth Fund summarized state accommodations to support telemedicine through the pandemic: "Twenty-two states changed laws or policies during the pandemic to require more robust insurance coverage of telemedicine." They used legislation, executive orders, and other agency actions, such as bulletins, notices, and executive orders from the Department of Insurance or a similar agency. Most of these states pursued changes via administrative action. The use of executive authority allowed states to move relatively quickly during the crisis, though it has meant that the new telemedicine coverage requirements are temporary. For example, seven governors included specific telemedicine coverage requirements in executive orders, binding during the public health emergency but expiring after that. In addition, some states used bulletins, notices, or executive orders from the Department of Insurance or a similar agency to enhance coverage. Administrative action also moved through various other vehicles (such as bulletins, notices, and executive orders from the Department of Insurance or similar agency) in states where sufficient statutory authority existed or an executive order created new authority without detailing specific requirements.

Eight states passed new legislation. Although the legislative process takes more time, it is necessary for permanent changes. Five states that did not previously require coverage of telemedicine services changed their policies during the pandemic, bringing the total number of states that currently require coverage to 40. In addition to securing this broad coverage obligation, states took other steps to enhance coverage and ensure access to health services while in-person care was limited during the pandemic.

However, waivers expired or were rolled back (e.g., Johns Hopkins stopped telemedicine for patients living in Virginia). By September 1, 2021, the Alliance for Connected Care (https://connectwithcare.org/) showed waivers in use in only 17 states.

Malpractice. Additional risks related to telemedicine include cases based on prescribing medicines across state lines without having conducted an in-person examination, failure to recognize when telemedicine is not adequate for the patient's illness, violating state laws, data breaches, diagnostic errors, informed consent, lack of policies and protocols, and others. Malpractice involved not following usual and customary procedures, inevitably ambiguous, shifting, and arguable during a pandemic. However, a Lexis-Nexis review of 551 court decisions (not cases settled otherwise) in October 2018 showed no recorded cases involving direct-to-consumer telemedicine practice; the same methodology covering January 1950 to January 2021 found no cases related to skin cancer diagnosis. The Public Health Emergency declaration covering the pandemic led federal and state governments to shield health care professionals from medical liability related to Covid care. Limited exceptions apply for gross negligence, criminal misconduct, and providing care while intoxicated. These protections preempted state and local laws inconsistent with the CARES Act. However, state laws that provide greater liability protections are not preempted.

A list of liability protections for in-state and out-of-state physicians, including volunteers, relicensed or recently licensed medical professionals, services provided through telehealth, and services consistent with expanded scopes of practice are available from the National Governors Association (https://www.nga.org/coronavirus/#states). In March 2020, HHS issued a limited waiver of HIPAA Sanctions and Penalties for the duration of the emergency (https://www.hhs.gov/sites/default/files/hipaa-and-covid-19-limited-hipaa-waiver-bulletin-508.pdf). Insurers vary in charging additional malpractice premiums when a practice is expanded to telepsychiatry (https://www.psychiatry.org/psychiatrists/practice/telepsychiatry/toolkit/telepsychiatry-malpractice-issues). Psychiatrists rarely are sued for malpractice. It is too early to tell if more use of telepsychiatry will make a difference.

A cost-effective, desirable future for medical malpractice litigation can be achieved by emulating the systems found in Denmark, Finland, New Zealand, Norway, and Sweden. It is accepted that adverse outcomes occur from medical treatment, so compensation is provided quickly to those who need it (similar to worker’s compensation). The economic incentive having been removed, clinicians convene to look at the treatment provided and determine fault, if any.

Cost Benefit/Effectiveness/Outcomes. The telemedicine efficacy literature has grown steadily with hardly any negative studies.

Recent applications have shown the efficacy of using telepsychiatry for:

- Buprenorphine maintenance
- Managing complex cases in primary care
- Factors associated with use and satisfaction in rural Virginia
- Use of a program to assist self-managed medical abortion
- Depressive symptoms in comorbid cardiac or diabetic patients
- A computerized adaptive scale for suicidal youth

A June 2021 Cambridge Review of the effectiveness of telepsychiatry surveyed three databases, Cochrane, PubMed, and PsychInfo. They identified 961 papers (English only), reducing those to 321 using exclusion criteria and removal of duplicates. Using thematic analysis, the authors found five themes that occurred across all papers in relation to the effectiveness of telepsychiatry.

- **Patient and clinician satisfaction**—there is consistently high patient satisfaction with telepsychiatry but lower clinician satisfaction, often resulting from cynicism and a lack of familiarity. Clinician satisfaction increases when clinicians trial telepsychiatry and become more positive about its uses.
- **Diagnostic reliability**—telepsychiatry was found to have high levels of interrater reliability equivalent to face-to-face consultations for common disorders, including mood and psychotic disorders, substance misuse, and dementia. It was also found to have high levels of diagnostic reliability across age groups.
- **Outcomes**—telepsychiatry has been found to reduce symptoms of common psychiatric disorders and improve quality of life in various environments, including emergency departments (EDs), inpatient units, and prisons. Telepsychiatry increases access to specialized services resulting in quicker access to treatment and reduced admissions.
- **Technology**—without adequate internet connectivity, clinicians cannot conduct an appropriate mental state examination, and the therapeutic relationship becomes challenging. Inadequate technology can impact the effectiveness of telepsychiatry among those who are socioeconomically disadvantaged and may not have access to appropriate technology.
- **Professional guidance**—there is a concerning lack of guidance around the use of telepsychiatry. There is a lack of standardization without clear protocols, and clinicians are unwilling to integrate telepsychiatry into their practice. The main concerns raised are confidentiality, consent, the appropriateness of specific patient groups, and emergencies.
- **Cost-effectiveness** is established by offsetting travel time and expense, as equipment and compliance costs have shrunk.

Internet

The internet was established in 1969 at the University of Southern California to link computers for national defense issues. Now it is accepted as a public necessity, like clean water or reliable electricity, with similar concerns about cleanliness, reliability, and access, but less regulation, policing, and enforcement. Psychiatrists and their patients use it as below.

Information on Disease, Diagnosis, Treatment, and Therapists. The internet has become a predominant source of data, with countless websites offering pages of information on health care and psychiatric problems. A Google search for “diabetes” yields “about 579 million pages.” In recent years, the diabetes searcher, despite having access to authoritative sources, has been inundated with popups advertisements for diabetes products. Seeking information about an illness or symptom may link to a symptom questionnaire and a suggested diagnosis, the more specific, the less trustworthy. Even so, some apparently reputable sites may actually be purveyors of false information. The pandemic underscores how disinformation brings money and infamy (both desired by wellness product sellers) to some purveyors and death to some believers. The antivaccine movement fosters disproven links to autism. Patients present with a mixture of information, disinformation, and questions. Visits were sometimes lengthened to answer questions; however, many physicians have learned what websites to recommend for reliable information. Often, physicians find that better-informed patients form better partnerships and tend to cooperate with treatment better. However, internet users can find almost anything they want and may refuse treatment based on overblown side-effect descriptions or demand a treatment based on a success story that does not apply to their circumstances. Hundreds of psychiatrists operate websites, setting forth facts about themselves and their treatments, which often are the path for patients to enter treatment. Many commercially operated websites may violate privacy policies with intrusive, unwanted follow-ups to those who contact them. Physicians are rated by sites that gather ratings and reviews; a malicious patient can be damaging. Periodically professional meetings include workshops on how to improve one’s web presence.

Support and Self-Help Groups. Support groups have evolved by diagnosis for most illnesses. Others deal with symptoms. These can lead to groups meeting in person or remotely, providing support, knowledge, and advice of varying helpfulness. Mental health organizations, such as the National Alliance on Mental Illness (NAMI), Mental Health America, and their local chapters offer hotlines and referrals for support and therapy. Numerous sites offer to find Alcoholics Anonymous (AA) meetings by zip code. Whatever the problem, you can probably find a group of people trying to deal with that problem. Some groups are hybrid, occasionally meeting in person and frequently staying in touch electronically. As voluntary associations are generally unregulated and discussions can veer off into unwanted directions, they sometimes ask a professional to be "present" or review or comment on posts (a "moderated support group"). Several hundred mental health professionals moderate such groups, carefully wording terms and conditions of participation. For example, a Yahoo search for "schizophrenia support groups" yields 2,670,000 sites.

Self-help groups are unmoderated support groups that emphasize traditional self-help mechanisms such as following steps to wellness. These groups offer low-cost, usually available support. Some follow the AA's 12 steps and offer sponsors. Members often agree to have instant messaging to reach anyone online. Email technology lends itself to mailing lists because addresses can be added to a message with ease and without costs, and emails typically include a "reply to all" option that makes it easy to respond at once to everyone who received the initial message. Variations in format allow user-friendly "chat rooms" where an email user can sign in and participate in a conversation with users who have signed in for that particular session, which typically lasts minutes or hours. However, asynchronous communications make an extension to days and weeks possible. Still other groups, such as Psychiatric Survivors (see https://www.psychiatricsurvivors.net/, but also https://mindfreedom.org, and https://www.madinamerica.com/2012/08/the-history-and-future-of-our-psychiatric-survivor-movement/) use their websites to oppose specific treatments, especially anything coercive, for example, hospitalization or involuntary medication. Other groups favor such treatments, tracing stigma to **untreated** mental illness. All support groups favor recovery and empowerment. "Recovery" does not mean "cure," but being able to move on with one's life while dealing with whatever remains of one's illness (possibly a disability, for which protocols and treatment are established). Empowerment means taking charge of one's illness and treatment, exercising choice, and protecting civil rights. Anything that smacks of being told what to do or what or how to think is objectionable. Coercive treatment is anathema, and medication is, at the least, suspect.

Online Advice, Diagnosis, and Therapy. It is estimated that thousands of mental health professionals (mostly counselors, social workers, and psychologists) are willing to pick up advice seekers online and work with them only by email. Many nonprofessionals or sued professionals justify this practice because those being helped would not otherwise come to therapy for various reasons, including geographic isolation, loss of privacy, and disability. Initially supported by venture capital from 1997 to 2000, but waning after 2001 with the appreciation of its limitations, it picked up with increased internet use. Many websites recruited therapists who provided diverse therapies before the pandemic, but there has been an exponential increase since. A Bing search for “online therapy” delivers 118,000,000 sites. Many recruit therapists who take insurance (e.g., Talkspace), and many sites offer medication online, including controlled substances (e.g., try.getcerebral.com sends the user to rx.getcerebral.com). Recent research topics include internet-delivered versus. in-person CBT for youths with obsessive-compulsive disorder (OCD) (followed by in-person visits for nonresponders) or a Cambridge database meta-analysis of CT for depression. However, research is not directed at exposing what may be a waste of time and money or harmful. It is generally agreed that mental health is worsening during the pandemic, yet therapists and prescribers of all types are scarce. As it seems a need is being met, issues of standards for good practice, quality, and enforcement will have to wait for more settled times.

Meanwhile, therapy sites are rated through user reviews, much like restaurants. Professional associations have not come forward with ethical standards. For example, the Clinical Social Work Federation, opposed in 2001 to unmet therapy, no longer mentions “online” or “unmet” in its Code of Ethics.

Prescription/Illicit Drug Sales. Physicians increasingly use electronic prescribing, mandated in some form, at least for controlled substances, in 25 states, with effective dates, mainly January 1, 2022, in another nine. All states now have prescription drug monitoring programs for controlled substances. Electronic prescribing is generally accepted, with a continuing objection related to lack of comparison shopping and privacy. Health insurers increasingly require patients to use favored online pharmacies, often avoiding contact with pharmacists. Some online pharmacies put prospective customers in touch with prescribers who will prescribe based on online questionnaires without further investigation. The Federation of State Medical Licensing Boards has barred using online questionnaires as the sole basis for prescribing medication. The Controlled Substances Act and the Food, Drug, and Cosmetic Act and been used to prosecute pharmacies that do not bother with prescriptions, reporting, and shutting down thousands of websites. Despite these efforts, the sale of medications over the internet without valid prescriptions has been a persistent problem. Pharmacies have moved offshore to countries with lax enforcement. Mail from China has been used to send fentanyl to the United States and other countries despite increased Chinese enforcement since 2019 (https://www.theguardian.com/world/2019/apr/01/china-fentanyl-substances-crackdown-us-opioids-crisis). A Yahoo search, “Where can I buy prescription drugs online?” yields 19,700,000 sites. A review of the 591 FDA press releases on enforcement of the past 3 years yields six cases related to internet prescription drug sales. The largest (4,256) website crackdown was in 1996. The FDA’s most wanted fugitives data have not been updated since March 2020.

The Washington Post’s expose on the distribution of 76 billion opiate tablets used Drug Enforcement Administration (DEA) data that the DEA had gathered but not released until required to do so under freedom of information (FOI) law. Tellingly, the pills had gone to many areas with few prescribers. The FBI’s Operation Disruptor announced in February 2020 that it had made 18,000 illegal drug purchases on the “*dark web*,” sites with encrypted identities. “Infamous examples of Dark Web sites include the Silk Road and its offspring, such as Dream Market. The Silk Road was a website for the buying and selling of recreational drugs, and a lot more scary things besides” (https://www.techadvisor.com/how-to/internet/dark-web). A Bing search in October 2021, “where can I buy opiates online?” nonetheless provides promising possibilities. Counterfeit, sometimes lethal, medications continue to be sold as legitimate medications. A September 2021 DEA warning pointed to fentanyl’s role in the 96,000 drug overdose deaths in 1920, as 26% of pills sold as something else (e.g., Adderall) contained lethal amounts. The internet’s role in getting get-high drugs to those who want them is paramount.

Legitimate prescription drug sales may have diminished as pharmacy chains engage in aggressive refill policies, more challenging to stop than start, but a small legitimate traffic persists in some psychotropic medications not available in the United States. Knowledgeable physicians typically can recommend safe sites. Some patients who do not have or do not want to use drug insurance coverage (e.g., wanting to stay out of as many databases as possible) have found their medicines available on the internet cost less than the copay they would have had to pay for using their insurance. As more medicines are made over the counter, they may be less expensive than prescription versions—some pharmacists in some jurisdictions are still prohibited from telling patients so.

Gratification: Sex, Games, and Addiction

PERSONAL EXPERIMENTATION/VALIDATION, SUCH AS DIFFERENT IDENTITIES OR REINFORCING BELIEFS. Pornography remains the top source of gratification from the internet, estimated to constitute 4% to 30% of total content. A Google search “pornography sites” yields 49,500,000 possibilities, but only 42,000 are recognized as active. For April 2020, the world’s top porn site, XVideos, amassed 2.92 billion views among 382 million unique visitors who averaged 12.5 minutes per visit. Almost any man with an internet connection has watched at least once, but Pornhub, the second most popular site, reports that 0.2% of men spent more than 2 hours a week on the site in 2019. It has not posted 2020 statistics, but use increased by 8 billion visits in 2019 from 2018, indicating that 2020 visits were higher. Fantasies related to any sexual appetite can be found, the purpose being sexual arousal and masturbation. Pornography remains controversial, seen by some as a victimless outlet for urges that might otherwise be hurtful, objected to by feminists who see women treated as objects. Excessive use (defined by the patient or significant other) brings many voluntarily to treatment.

The internet is used for dating apps, another exponentially increasing way of connecting since pandemic lockdowns left few choices. Some apps promote recreational sex and extramarital affairs. In the October 2021 rating of top sites, Adult Friend Finder (78 million members) and Ashley Madison (40 million) led the more specialized sites. Problems related to false presentations, exploitations, and crimes are covered well in the media as cautionary. Couples have been known to meet on the internet, fall in love, and arrange to marry, only to find they should have verified one another's sex and gender identities. The movie "You've Got Mail" showed the use of email as a way of expressing kinder, nobler feelings than Tom Hanks' character could do in real life as a cutthroat businessman. However, studies on email show that communications are more likely to be bitter, angry ("flaming"), suspicious, or paranoid than what would have been said in a face-to-face meeting. Easy, impulsive, quick responses play a role. Also, there are fewer cues (facial expressions or nonverbal communication) to facilitate empathic civil discourse.

The internet can offer not only anonymity but also a choice of other identities, such as Second Life (http://www.secondlife.com) which describes itself as "a 3-D world entirely created by its Residents". (Since its founding in 2003, 98,944 regions have been created by 68, 687,941 of them, of whom 45,297 were online during a check on October 12, 2021.) They create and chat using voice and text chat, buying and selling with Linden dollars, convertible to U.S. dollar (as of October 7, 2021, 320 Linden Dollars equal $1). Other alternative life sites include Mozilla Hubs (free, open source), VRChat (free), Tower Unite (paid), and Furcadia (free). Alternate lifers tend to be more colorful, less restrained, or criminal as the sites allow crime and deceit without penalty. Psychiatrists become involved according to whatever problems result.

Although "internet addiction" is a widely used lay and professional term, it was not included in DSM-5 in 2014. Most apparent "addicts" have been found to decrease excessive use and pursue specific knowledge and communication goals rather than surf aimlessly. Internet gaming was included as warranting further study. Its status was updated by the American Psychiatric Association advice to the public on its website (https://www.psychiatry.org/patients-families/internet-gaming):

> *Whether internet gaming should be classified as an addiction/mental disorder is the subject of much debate and a growing body of research. There is neurological research showing similarities in changes in the brain between video gaming and addictive substances.*

> *A study published in the American Journal of Psychiatry in March 2017 sought to examine the validity and reliability of the criteria for internet gaming disorder, compare it to research on gambling addiction and problem gaming, and estimate its impact on physical, social, and mental health. The study found that among those who played games, most did not report any symptoms of internet gaming disorder and the percentage of people that might qualify for internet gaming disorder is extremely small.*

> *The research involved several studies of adults in the U.S., United Kingdom, Canada, and Germany. They found that more than 86 percent of young adults ages 18 to 24 and more than 65 percent of all adults had recently played online games. The percentages of men and women who recently played were roughly equal. However, the research is mixed on whether those who met the criteria for internet gaming disorder had poorer emotional, physical and mental health than those who did not meet the criteria.*

> *The researchers found that 0.3 to 1.0 percent of the general population might qualify for a potential diagnosis of internet gaming disorder. The authors suggest an important distinction between passionate engagement (someone enthusiastic and focused on gaming) and pathology (someone with an illness/addiction). Whether the person is distressed with his/her gaming may be the key factor distinguishing the two.* (Reprinted with permission from the Psychiatry.org, “Internet Gaming,” James Sherer, section “Research is Ongoing” [Copyright © 2023]. American Psychiatric Association. All Rights Reserved.)

However, according to WHO:

> *Gaming disorder, with its online and offline variants, has been included in the 11th edition of the International Classification of Diseases (ICD-11) as a clinically recognizable and clinically significant syndrome, when the pattern of gaming behaviour is of such a nature and intensity that it results in marked distress or significant impairment in personal, family, social, educational or occupational functioning.* (Reproduced from World Health Organization: Inclusion of "gaming disorder" in ICD-11, © 2018. https://www.who.int/news/item/14-09-2018-inclusion-of-gaming-disorder-in-icd-11)

ICD-11 was released in mid-2018. Health concerns associated with gaming behavior are not limited to gaming disorder but also include other aspects of health (e.g., insufficient physical activity, unhealthy diet, problems with eyesight or hearing, musculoskeletal problems, sleep deprivation, aggressive behavior, and depression) and psychosocial functioning. Studies suggest that gaming disorder affects only a small proportion of people who engage in digital- or video-gaming activities. However, people who partake in gaming should be alert to the amount of time they spend on gaming activities, mainly when it is to the exclusion of other daily activities, as well as to any changes in their physical or psychological health and social functioning that could be attributed to their pattern of gaming behavior.

SOCIAL MEDIA. In October 2021, "app engagement" emerged as key to getting apps downloaded and used as Facebook was alleged to choose growth over beneficence and concealed data showing the harmful effects of apps. Some Instagram users, especially teenage girls, felt worse about their appearance, while other surveys reported increases in suicidal ideation, insecurity, and fear of ostracism if quitting use. Anxiety and depression, already widespread (20% of Americans thought to have anxiety disorders), heightened during the Covid pandemic as anger (often displaced) and frustration, fueled by disinformation and political polarization. App engagement research starts with the initial screen and leads to a user clicking on links that lead deeper into the subject. Engagement metrics, extensively researched, are bolstered by artificial intelligence to generate algorithms that promote more engagement ("engagement-based ranking"), often leading to salacious, extreme, attractive, but harmful sites that are meant to keep the user online longer. Facebook and its apps were alleged to have chosen links that attracted users because of sensationalistic falsities. Several studies have shown that falsities spread faster on social media than truth, the briefer, the faster, as on Twitter (X) (daily use in 2021: 199 million, 69 million in the United States). Facebook was termed “morally bankrupt” for not doing more to spread the truth and stop the spread of disinformation. It responded by pointing out that the mountains of leaked data were based on user surveys rather than controlled studies and calling for government regulation of social media. However, recent polling, such as that of 1,638 users (ages 16+) reported on October 8, 2021, showed averages of 20% to 25% feeling more anxious, depressed, alone, left out, and angry after Facebook and Instagram use, wanting to stop using but “can’t stop.” Those who cannot stop probably define their inability to do so as addiction. Aside from gaming, pornography (cybersex), and social media (cyber-relational), overshopping for goods is a significant problem, for which several measurement scales are helpful, especially for convincing patients they have problems. About 30% of those who describe themselves as addicted reported using the internet to escape negative feelings because it was always available at a low cost. This percentage is slightly lower than a recent poll of social media users who described themselves as unpleasantly addicted to social media but unable to stop.

Government regulation is likely, to focus on the alleged algorithms, disinformation, and spread of hate and violence. For example, ISIS online recruiting was very effective, using algorithms that picked up potential recruits and led them through a series of websites.

Internet Treatment Issues. The dependency/addictive component of the issues described above is similar to those of other addictions: withdrawal to less impaired use, often periods of abstinence. Initial treatment may involve one of the thousands of online help websites, but treatment success will depend on engagement with more regarding offline activities. Those who describe being unable to stop using the internet despite negative or joyless feelings may have an obsessive-compulsive dimension amenable to OCD treatments. Issues of disinformation, identity, hate, polarization, and conspiracy involvement are complex; findings from terrorism involvement and disengagement are helpful. Support groups and psychotherapy are beneficial.

Cyberbullying of adolescents is a particular problem, often unreported (http://www.bullyingstatistics.org). Over half of adolescents and teens have been bullied online, and about the same number have engaged in cyberbullying. More than one in three young people have experienced cyberthreats online. Over 25% of adolescents and teens have been bullied repeatedly through their phones or the internet. Over half of young people do not tell their parents when cyberbullying occurs.

There are increasing reports of social media-induced sociogenic illnesses. For example, during the pandemic, neurologists began to encounter patients, particularly teenage girls, with unusual Tourette-like tics, which appeared to be caused by watching TikTok videos of people reporting to have Tourette syndrome.

Virtual Reality

Virtual reality as therapy was pioneered in the early 1990s by Max and Sarah North and was used for various phobias. It usually functions as a type of desensitization therapy. Tips for more effective practice are available (see the article by Krzystanek and colleagues in the references). Several journals (e.g., Virtual Reality, Frontiers of Virtual Reality, International Journal of Virtual Reality) report generally positive research. Adverse outcomes, infrequent, include “cybersickness” and transient identity and reality loss.

MEDICAL RECORDS

Medical recording accompanied the developments of writing and medical care in ancient civilizations. The earliest known medical record is the Edwin Smith Surgical Papyrus, dated to between 5,000 and 4,500 years ago, a treatise that includes 48 typical cases, mainly head injury, with histories ranging from head trauma to infection. Although format and content have greatly expanded over the years, the medical record mainly describes past events recorded on paper. Carole Siegel and Susan Fisher’s unique study of the psychiatric record can be summarized as generally applying to records. Practitioners with access to patients go to the patient, whereas those who cannot get to patients have to use the record. However, many records are illegible, and finding data can be complex.

Early efforts to convert to electronic formats were inspired by the ease of retrieval and legibility but suffered from overexpectation, high cost, nonstandardization of data elements, and other key factors that impeded accessible communication among physicians. Despite a lack of political support, some institutions developed excellent records, but there was little spread. The current effort began in 2004 with federal initiatives: The ONCHIT and an HHS report laying out a 10-year plan for federal, state, and local leadership. It has resulted in multiple public–private partnerships, including the Health Information Technology Standards Panel to define elements and standards and the CCHIT. electronic medical records (EMRs) are expected to improve patient care by reducing medical errors and clinical decision support. They are also expected to reduce care costs by reducing overutilization and promoting continuity of care as clinicians communicate individually or in groups through RHIOs and HIEs. For example, the Veterans Administration's excellent EHR makes it possible to retrieve a patient's record (with permission) anywhere, including all diagnoses, medications, and treatment. This ability has proven to be of great benefit after local records are destroyed, such as happened due to Hurricane Katrina.

Problems in EHRs

Despite the legislation, funding, and universal consensus promoting EHRs, they are cited in every survey of physician burnout as one of the two leading causes of physician burnout (EHRs were marketed to ease the other, prior authorization). Both issues are related to documentation demands imposed from outside the doctor–patient relationship. Both issues have been promoted to improve patient care and reduce costs, but numerous studies show increased costs related to EHRs and prior authorizations. Physicians have been shown to spend as much or more time with their computers as with patients. Workarounds to shorten tasks lead to the causes of EHR malpractice listed below and create sloppiness. Errors can be made in the flash of a click on the wrong item in a table and not picked up, a particular type of typo.

The sources of EMR frustration and bloat include the following:

- Insurance carriers, for profit (mostly) and not for profit, that set documentation requirements conduct audits and withhold payments for services already rendered, sometimes demanding the return of payments already made.

- Accreditors and remedies for deficiencies. Typically, a record problem found on review results in zealous attempts to ensure that every progress note addresses the deficiency, so the record bloats with each added deficiency remedy. If inspectors and accreditors are not satisfied, reimbursements and institutional reputation will suffer.
- The lack of software usability tests led to sloppily designed and cobbled-together systems. Examples are programs requiring users to enter data via one browser but use a different browser for drug ordering.
- Payment incentives, especially for evaluation and management (E/M) coding justification.

The Social Security Act 1862 (a)(1)(A), effective January 1, 1991, defined medical necessity as the basis for reimbursement. Concerns developed over the years that doctors were being paid more for **doing** (e.g., a surgical procedure) than **thinking** (e.g., taking a history, examining, formulating a treatment plan, prescribing, and organizing care for an obese, homebound patient with arthritis, chronic obstructive pulmonary disease, and diabetes). Evaluating and management codes, ranging from simple to complex to reflect levels of thought, were published in 1995 and 1997, well before EHRs. Documentation in the EHR is reviewed to ascertain whether E/M codes are justified. The more complex codes bring greater reimbursement, hence the more documentation. The CMS Meaningful Use requirements (https://www.cms.gov/Regulations-and-Guidance/Legislation/EHRIncentivePrograms/Downloads/EHR_Medicare_Stg1_BegGuide.pdf) set 13 core objectives, 5 menu objectives, and 9 quality measures, some of which require EHR content that can be described as incomplete and must be expanded. The 2-year anniversary of “Patients over Paperwork was celebrated in 2019: On “October 29, 2019, CMS celebrated the second anniversary of Patients over Paperwork, which began with an RFI that yielded more than 3,000 data points on more than 1,100 different issues. To date, Patients over Paperwork has yielded estimated savings of $6.6 billion to the medical community with a reduction of approximately 42 million hours of burden through 2021.” (https://www.cms.gov/files/document/november-2019-patients-over-paperwork-newsletter.pdf, which describes some achievements unrelated to reducing burden, such as payment changes). The need for more burden relief prompted the 21st Century Cures Act provision (Section 13103, amending HITECH) that led to *The Strategy on Reducing Regulatory and Administrative Burden Relating to the Use of Health IT and EHRs*, final in February 2020 after stakeholder comment (1,400 pages) on the 2019 draft (https://www.healthit.gov/sites/default/files/page/2020-02/BurdenReport_0.pdf). Four work groups, consisting of HHS workers, made recommendations ("consider…improve") for clinical documentation, HIT usability and the user experience, EHR reporting, and public health reporting. Implementation will require specific recommendations, with the change expected in 3 to 5 years. The strategy does not suggest incentives for brevity or finding methods for reimbursement apart from clinical notes. A resolution to separate clinical notes from reimbursement is being considered by the Medical Society of the State of New York.

Interoperability

Exchange of patient HIT is a rare issue that has virtually universal political support. Under HIPAA, the HITECH of 2009, and the Affordable Care Act (ACA) of 2010, voluntary associations of covered entities were set up and variably funded: RHIOs, Community Health Information Exchanges (CHINs), and Health Information Exchanges (HIEs). These are viewed as the primary hope for increasing quality and safety and decreasing overutilization and fraud, becoming the Nationwide Health Information Network (NHIN), reported positively (https://pubmed.ncbi.nlm.nih.gov/30234636/) as having "implemented secure exchange of health records through utilization of the Internet." The NHIN has greatly assisted in achieving the goals of the HITEC Act by promoting the adoption of Meaningful Use. Epic introduced a Health Information Exchange platform, Care Everywhere, facilitating Health Information Exchange availability. The purpose of this research was to determine the impact of NHIN and Epic Care's Care Everywhere on health care to determine whether their use in the ED has increased. The study relied on a literature review. Twenty-eight sources were referenced. With the NHIN implementation, repeated visits were decreased, visit times became faster, and charges were lower. The ED reported significant benefits in sharing clinical information. The NHIN implementation throughout the ED has increased the quality of health care; duplicated tests and drug usage were determined, and a reduction of the ED length of stay was also achieved. However, the NHIN is **not** a central database containing PHI that can be looked up from an emergency room trying to help a patient. Instead, the NHIN is a set of standards and policies. RHIOs exist in most states, statewide or local, currently adequately funded but not immune from organizational problems. New York consolidated its RHIOs down to eight. California's RHIO shut down in 2010; instead, the California Trusted Exchange Network is used for PHI exchanges. RHIO requests for funding from users have been strongly resisted, not seeing the point of funding what they see as unnecessary bureaucracy. Apart from RHIOs and HIEs, providers who know they are taking care of a particular patient can exchange information according to traditional consent methods (as a covered entity if transmitted electronically). Software incompatibility has been a significant barrier. Although CMS has delayed some payer-to-payer interoperability enforcement, two rules took effect in July 1, 2021, explained in FAQs posted in September 15, 2021 (https://www.cms.gov/Regulations-and-Guidance/Guidance/Interoperability/index).

Malpractice

Some studies show that EMR use reduces risk because the record is entirely legible and retrievable, using software that prompts completeness and consistency. However, law firms seeking cases argue that EHRs increase the risk for lawsuits (https://www.jcreiterlaw.com/posts/8-reasons-your-electronic-medical-records-may-result-in-a-medical-malpractice-lawsuit/). Various design flaws, outdated information, errors in voice recognition, and other transcribing errors can put practitioners at risk. User error, such as inappropriate copying and pasting, can also lead to medical negligence. For example, doctors may erroneously copy and paste information from the last patient visit into the record while leaving out what has changed. Similarly, autopopulate functions can add erroneous information. Simple typos can also have disastrous results if they result in a wrong diagnosis or procedure. Finally, the record can harm the doctor–patient relations, cutting down on direct interactions (most of us are familiar with the doctor who seems more interested in their screen than us), or causing burnout and exhaustion.

The Medical Society of the State of New York suggested simply using clinical notes solely to communicate with other clinicians, arguing that clinicians become a party to fraud when the EHR is used for billing in their name, that they are required to report examinations barely done, or attest to yes-or-no suicidality when the situation is ambiguous.

Privacy and Security

EHR regulations carry a substantial documentation burden, both for an overall plan for protecting PHI and documenting informed consent, with additional requirements that each individual practice document how it will protect PHI in electronic media. The more secondary sources of PHI exist, the more difficult it is to determine where confidentiality may have been lost. Such secondary sources can be helpful to individuals seeking data on a particular patient. Such people may be criminals, unethical private investigators, and others. They proceed by hacking into databases and retrieving PHI that might bear on competence, custody, divorce, and other adversarial situations. They, rather than organizations, may be interested in the content of specific emails. Such individuals have broken into offices to get individual patient records in the past. Computer break-ins can be simple, depending on the relative skills of the hacker versus the burglar, and may leave no trace. Although current guidelines for the transmission and storage of PHI recommend password protection and encryption, it would be unwise to expect that such safeguards would prevail against a specific, determined, individual attack. Penalties for criminal acts related to medical records have existed for years with variable enforcement. The risk of violation of a competently protected personal medical record (PMR) probably is less than that of a paper record, whereas a mass of EHRs may be subject to attack by a group seeking money rather than specific information on one individual.

Despite almost weekly reports of confidentiality lapses involving thousands of people, complaints about the mere few hundred criminal complaints and just six convictions for privacy violations under the HIPAA from the first in 2004 through April 2015 resulted in the HITECH breach reporting, and penalties cited above, summarized by HHS (https://www.hhs.gov/hipaa/for-professionals/compliance-enforcement/data/enforcement-highlights/index.html) Since the compliance date of the Privacy Rule in April 2003, OCR (Office of Civil Rights) has received over 272,923 HIPAA complaints and has initiated over 1,101 compliance reviews. Ninety eight percent of these cases have been resolved (268,469). In addition, OCR has investigated and resolved over 29,081 cases by requiring changes in privacy practices and corrective actions by providing technical assistance to HIPAA-covered entities and their business associates. Corrective actions obtained by OCR from these entities have resulted in systemic change, affecting all the individuals they serve. OCR has successfully enforced the HIPAA Rules by applying corrective measures in all cases where an investigation indicates noncompliance by the covered entity or their business associate. OCR has settled or imposed a civil money penalty in 100 cases, resulting in a total dollar amount of $130,980,482.00. OCR has investigated complaints against various entities, including national pharmacy chains, major medical centers, group health plans, hospital chains, and small provider offices.

In another 13,294 cases, the investigations found that no violation had occurred. In addition, in 49,553 cases, OCR has intervened early and provided technical assistance to HIPAA-covered entities, their business associates, and individuals exercising their rights under the Privacy Rule without the need for an investigation.

In the rest of the completed cases (176,541), OCR determined that the complaint did not present an eligible case for enforcement. These include cases in which:

- OCR lacks jurisdiction under HIPAA. For example, in cases alleging a violation by an entity not covered by HIPAA
- The complaint is untimely or withdrawn by the filer
- The activity described does not violate the HIPAA Rules. For example, in cases where the covered entity has disclosed PHI in circumstances in which the Privacy Rule permits such a disclosure

From the compliance date to the present, the compliance issues most often alleged in complaints are compiled cumulatively, in order of frequency:

- Impermissible uses and disclosures of PHI
- Lack of safeguards of PHI
- Lack of patient access to their PHI
- Lack of administrative safeguards of electronic PHI; and
- Use or disclosure of more than the minimum necessary PHI

The most common types of covered entities that have been alleged to have committed violations are, in order of frequency: general hospitals;

private practices and physicians; outpatient facilities; pharmacies; and community health centers.

OCR refers to the Department of Justice (DOJ) for criminal investigation appropriate cases involving the knowing disclosure or obtaining PHI in violation of the rules. As of the date of this summary, OCR made 1,182 such referrals to DOJ.

Breaches Increase

HHS is required to report breaches annually to Congress, which shows increases in the numbers of people whose data were breached: Per the HIPAA Journal: “More large healthcare data breaches were reported in 2020 than in any other year since the HITECH Act called for the U.S. Department of Health and Human Services’ Office for Civil Rights to start publishing healthcare data breach figures on its website.” In 2020, health care data breaches of 500 or more records were reported at a rate of more than 1.76 per day. In addition, 2020 saw 642 significant data breaches reported by health care providers, health plans, health care clearinghouses, and business associates of those entities—25% more than 2019, which was also a record-breaking year. More than twice the number of data breaches are now being reported than 6 years ago and three times the number of data breaches in 2010.

Key Takeaways

- Twenty-five percent year-over-year increase in health care data breaches
- Health care data breaches have doubled since 2014
- 642 health care data breaches of 500 or more records were reported in 2020
- 1.76 data breaches of 500 or more health care records were reported each day in 2020
- 2020 saw more than 29 million health care records breached

One breach involved more than 10 million records, and 63 saw more than 100 K records breached. Hacking/IT incidents accounted for 67% of data breaches and 92% of breached records; 3,705 data breaches of 500 or more records have been reported since October 2009; 78 million health care records have been breached since October 2009.

Ransomware

Rather than breaching PHI and selling the data, criminals have found that hacking into a system and paralyzing it until a ransom is paid is very profitable. Ransomware payments reached over $400 million globally in 2020 and topped $81 million in the first quarter of 2021 (https://www.whitehouse.gov/briefing-room/statements-releases/2021/10/13/fact-sheet-ongoing-public-u-s-efforts-to-counter-ransomware). The health care sector, which was already stretched and stressed by the pandemic, continued to be heavily targeted in 2020 with at least 560 facilities being impacted in 80 separate incidents (an attack on a health system can impact multiple facilities) (https://blog.emsisoft.com). These data do not include lost lives or revenue.

CLINICAL ISSUES

These include symptoms, diagnoses, and defense mechanisms. Although email and telepsychiatry share some of the same indications, the mode of initial interaction may vary. With email, the patient and therapist generally have met on their own, either face to face or online. Telepsychiatry presently consists mainly of consultations, with referrals arranged by someone where the patient is located. Availability of consultant expertise usually is the key indication. Home health care monitoring can be beneficial for situations where a home visit would have been used. Both may be useful to overcome limitations of access, distance, and disability. Both are valuable adjuncts to therapy in situations where the patient and therapist meet face to face but want more frequent contact. Its format lends itself, for example, to the sort of written daily homework expected in cognitive behavioral therapy (CBT). It may be helpful as a way of getting patients into treatment that they otherwise would not seek, but that should then progress to more substantial involvement via telepsychiatry or face-to-face contact. As webcams have come into wider personal use, some patients have found telepsychiatry to be more convenient and of lower cost than travel to a therapist’s office.

Virtual Reality

Experiments showing efficacy in various forms of situational anxiety are convincing. Most phobias and fear-provoking situations can be simulated in virtual reality therapy (VRT). Investigations of VRT's usefulness in OCD, attention deficit disorder (ADD), and PTSD are underway.

Limitations

The principal limitations of email are related to the data not being transmitted or available. There are potential problems in identifying both the patient and the therapist. Investigations of those offering online services found that many did not give their professional credentials or were incomplete (e.g., "MS" in a context that implies that the degree is in counseling when it may not be). Similarly, potential clients often give themselves fictional names. Although this is seen as a way of preserving anonymity, without which help might not be sought, therapy cannot progress far without more disclosure. Not all deception is deliberate. As noted earlier, patients may feel that they have a different identity on the internet, leading to their portraying problems consistent with that identity rather than their identity in real life. Although controlled studies show that patients divulge facts more rapidly and entirely to computers, most studies were done with substance abusers before the internet and the rise of confidentiality concerns. Computer-based assessments have not replaced live interviews because communicating facts does not convey how people think or feel.

On the other hand, the disinhibition of emotion noted in unstructured emails is an indication for therapy where defenses must be overcome and a limitation if the feeling is impulsive or marginally related to the issues for which therapy is sought. These same limitations apply to support and self-help groups. Therapist limitations must also be noted. Extensive use of email is not recommended for therapists who have not mastered expressive writing, typing, use of computers and the internet, encryption, security of electronic data, and how to deal with computer glitches. Therapists must be aware of how they may seem online, be able to correct miscommunications in both directions and be able to shift modalities (e.g., from online to face-to-face communication) when indicated.

Telepsychiatry, Online Therapy

A person may get very good at e-therapy and working on the internet without this result generalizing to the physical world. So-called “cyborg theory” has been invoked to describe the mechanisms whereby the animal–man boundary blurs, along with the man–computer boundary.

Reports have described predators taking advantage of victims met on the internet. Online therapists report referring patients for face-to-face therapy, but they often view this as a desirable progression rather than a complication. Chat room addicts can take over self-help groups. Patients and therapists may present false identities. Predators can pick up vulnerable people and develop private correspondences that lead to disaster.

Despite the widespread use and general acceptance of telemedicine, about two-thirds of patients who had it reported in two polls in July and September 2021 (https://media.npr.org/assets/img/2021/10/08/national-report-101221-final.pdf, 42% used, 82% satisfied, but 64% would have preferred in person) that they preferred in-person visits to physicians, despite travel time and cost and waiting room issues. In addition, several studies show that more oxytocin (promoting bonding, trust, affection) is produced when people meet in person. Limitations reported ranged from for e-therapy (https://nymag.com/press/2021/03/on-the-cover-of-new-york-the-lunacy-of-app-based-therapy.html) to telesurgery (https://jamanetwork.com/journals/jamasurgery/fullarticle/2778018), while new insurance requiring the first nonemergent visit be virtual (https://kffhealthnews.org/news/article/virtual-first-insurance-plans-telemedicine/) has appeared.

Contraindications

Both email and telepsychiatry are less desirable when the patient and psychiatrist can meet face to face. However, the patient may continue using a support or self-help group. Psychiatrists should always be sensitive to the possibility that VRT is contraindicated for patients with serious medical problems and patients taking medications with significant physiologic or psychological effects. Flickering images, especially at 8 to 12 Hz, may produce symptoms ranging from headaches to epileptic seizures, so no frame replacement speeds that approach these frequencies should be used.

Email Journaling

A patient moved to another country and put his daily journal on Google Drive. The psychiatrist reviews the entries every week and makes notes daily where appropriate. The patient, previously repeatedly hospitalized for psychoses, became unimpaired.

Telepsychiatry

- A second-opinion consultant elicited new symptoms, substantiated a different diagnosis, and recommended treatment that proved to be effective.
- A well-known psychiatrist performed what he considered an excellent interview but missed that the patient was increasingly resentful about the picture-in-picture showing her. She motioned to have the local crew on-site cover it, which they did, with a sheet of paper covering part of the consultant's image. None of this was conveyed to the consultant, who was now somewhat walled off. The patient continued to smile while the consultant suggested that her previous head trauma could benefit from a neurologic workup and reduce her need for 25 mg of diazepam a day, but observers in the room noted that her shoulders squared and her posture conveyed belligerence. The consultant's first clue that the interview had gone badly was at the end when the patient responded to his asking if she had any questions. She glared and said, "Yeah, what do I do the next time I'm feeling suicidal and don't want to call anyone?"

Virtual Reality

- A patient with social phobia was treated in her psychiatrist’s office with a virtual reality program that provided a series of social stimuli, adding and subtracting as she coped successfully with each. She realized she had a particular problem with older men and developed skills in dealing with them.
- A similar patient was never able to accept that virtual reality had anything to do with his problems and instead benefited from medication, which was decreased as he developed new skills in handling real-life challenges.

Electronic Health Records

Danielle Ofri describes making mistakes from being rushed, having multiple records open simultaneously, typos with consequences, miscommunications with patients, how EHRs negatively affect mindsets and slow down patient care. (https://danielleofri.com/tag/ehr/)

ETHICAL ISSUES

Ethical issues in electronic communication have been explored, and consensus statements are available for the individual practitioner. While the general principles of medical ethics apply, special consideration is required to explain where data are stored—how to be accurate without undue alarming. As pandemic restrictions ease, there will be more choices about using telepsychiatry or not. A review of the ethical challenges in conducting telepsychiatric assessments that might lead to involuntary detention in Britain urges they be avoided as much as possible, returning to previous prohibitions. Ethical issues will also depend on theoretical considerations and the practicality of maintaining confidentiality. The ethics of distributive justice have been used to show that, despite the current trend of improving quality, lowering costs, and more widespread use of electronic media, not all those in need are reached. A therapist referring patients to an online support group will face an added ethical burden to maintain contact with the group and have some sense of what is occurring, given that such groups can change rapidly. Ethical issues around identity and disclosure will continue as patients want to know what is stored and where and how such information can be accessed.

In all cases, the therapist must explain the procedure in detail, how data are stored, safeguarded, and transmitted, and the limitations and potential complications of the treatment. Informed consent must be obtained and must now include warnings that a determined hacker can get into almost any website or communication given enough time, funding, and expertise. Blockchain technology, currently being explored for medical records, may prove an exception, but only if the chain of custody as data are moved remains secure. Therefore, it is wise to record the consent both in writing and electronically.

For EMRs, the ethical dilemmas of data entry issues include entering enough to meet documentation efforts while still trying to make the record clinically useful. “After the Storm” (Siddhartha Mukherjee [MD], Topic Coronavirus Chronicles, New Yorker, May 4, 2020, p. 29) reports clinicians becoming aware of clotting as part of the COVID-19 clinical picture and finding the EMR could not be searched. Details from the clinical encounter have been used to ask for an increased payment, resulting in more details being specified to get more reimbursement, for example, Medicare chart reviews yielding an additional $6.75 billion charges, while simultaneously bloating the EHR beyond any useful clinical legibility (Billions in Estimated Medicare Payments From Chart Reviews Raise Concerns. OEI-03-17-00470, 12/10/190 (https://oig.hhs.gov/oei/reports/oei-03-17-00470.asp). EHRs have been used to perpetrate other financial frauds despite apparently involved clinicians being unaware of the fraud (Kaiser Health News, 12/23/19: “Electronic Health Records Creating A ‘New Era’ of Health Care Fraud”). The records also contain unseen risks to patient safety (KHN 3/31/19: “Death by 1,000 Clicks: Where Electronic Health Records Went Wrong”). Physicians must also be careful not to enter data that might increase the marketability of breached health care records, currently (October 1, 2021, https://www.imprivata.com/blog/healthcare-data-new-prize-hackers) up to $250/record.

Clinicians are often given templates and language that include everything necessary to get reimbursement, often stating that more was done than actually was the case, for example, a neurologic examination or detailed mental status. How much to delete becomes an ethical dilemma.

THEORETICAL ISSUES

Theoretical issues may relate to (1) the use of electronic media per se, (2) the selection of data to be recorded, (3) acceptable and reimbursable medical practice, (4) identity and the internet, (5) treatment of pathologic internet use, (6) uses of HIT, (7) privacy and security, (8) development of an interconnected information society, (9) HIT and health care change, and (10) possible therapeutic uses of games.

Electronic Media

Microprocessors are the only major commodity that continues to do more and more for less and less cost. Moore’s law dictates that the number of microprocessors that can be fit on a chip will double every 2 years has held for 50 years. As of 2019: “Moore’s Law is still valid and in good condition. It did not die, did not slow down, and is not even sick… transistors can reach to 0.1 nanometers” (https://xiaomidna.com/news/industrial-scientific/moores-law-is-still-valid-transistor-will-achieve-0-1nm). Individuals are surrounded by devices using microprocessors that can be linked by varied communication modes that have become faster and cheaper while carrying more data. Sensors in everyday devices can be hacked. In 2014, a refrigerator was sending fundamentalist Christian messages to its owners. We live in a world of interconnected smart things. Many of these devices have multiple uses, including internet access, and simultaneously converge in multiple uses while being differentiated according to user preference. Technology is evolving toward the constant use of mobile devices. Individuals often are unaware of using microprocessors and the internet as auxiliary thinking devices, but the differences in memory retrieval from one’s brain versus the internet are immense. Calculators and spreadsheets outstrip merely human efforts. People vary widely in the amount and frequency of media use for communication, but there is a general increase as communication becomes cheaper and faster. New communication formats continue to arise.

Selection of Data to be Captured

Any electronic data storage involves not capturing other data, but selection must now contend with too much available data, such as websites, social media postings, and bloated EHRs. What is significant? Conversely, anything less than in-person interaction with a patient means some data will be lost, even with the capacity to magnify images and move cameras around. Who controls the camera makes for crucial differences. Whereas some data reduction is desirable, as one's attention inevitably focuses on one thing or another, some choices may miss the key points. E-therapy captures only words without tone of voice, inflections, and the social cues that voices carry. Telephones do not capture facial expressions. Telepsychiatry may focus on the smiling face of an apparently open, cooperative person while missing the squared-off shoulders and rigid posture of controlled hostility. The use of multiple cameras and observers may increase data input, but increased equipment expenses and observer time still do not close the gap between being there and dealing with the reality of the situation. The decision to use electronic media depends on whether the advantages of such use outweigh the disadvantages of data reduction.

Acceptable and Reimbursable Medical Practice

Acceptability is determined mainly by professional associations based on evidence. The Centers for Medicare and Medicaid determine reimbursability in the United States for Medicare and Medicaid Services (CMS), setting standards most commercial insurers accept. Clinicians experience CMS reimbursement as easily obtained, albeit sometimes so low that clinicians choose not to participate, more often in Medicaid. In general, for-profit insurers pay more but may make reimbursement difficult, supposedly in the name of quality, but clinicians suspect saving money is the main motive. Reimbursement disputes often involve E/M coding and documentation thereof. EHRs may progress quickly to being acceptable, reimbursable, and required in some settings, but so far, many physicians see them as user-unfriendly and overly reliant on templates and documentation requirements for billing and reimbursement. Many high-volume, high documentation requirement settings use medical scribes, numbering more than 100,000 in 2021, estimated to be 154,000 by 2028. The use of medical scribes will be an inverse measure of EHR bloat. Psychiatrists' interest in using EMRs varies according to the practice setting, the volume of patient visits, and patient and psychiatrist concerns about privacy. Avoiding documentation, electronic data storage, and other problems cited above leads to not accepting electronic billing or taking health insurance reimbursement.

Increasing the EHR burden despite efforts to reduce it poses whether the EHR can be all things to all stakeholders. Alternatively, the clinical note would be simply for brief communication with other clinicians, not used for reimbursement. Such EHR systems in other countries draw few complaints.

Identity and the Internet

Increasingly, people prefer to work with computers and disclose more facts to impersonal electronic media than they do face to face with live interviewers. Detailed personal information often is made available to everyone on social websites such as Instagram, Facebook or Twitter (currently rebranding to “X”) by individuals who are shy and reserved in person. Several dozen studies show that patients give more detailed and accurate substance abuse histories in computer interviews than live interviewers, although feelings about the substances used are not conveyed well. This finding has led to the widespread practice of having patients fill out forms and screening instruments before seeing a physician in person or while developing PHRs. Electronic media for communication avoids dealing with reactions from real people one is facing.

Virtual reality practitioners note that each person brings their background into a virtual reality experience. They describe a “virtual presence,” which increases as patients spend more time in the virtual environment. Doing so involves giving up some sense of presence in the real world. Although VRT was initially patterned after systematic desensitization as practiced without electronic assistance, some of its practitioners now speculate that it is oriented more toward neurophysiologic information processing theory and the accelerated integrative information processing paradigm presented by Frances Shapiro (https://www.emdria.org/public-resources/emdr-therapy-beginnings-francine-shapiro/). Patients in VRT typically would not communicate back to their therapists in the physical world but instead seemed to be reliving their previous anxiety-provoking experiences. Other therapists point to the flight simulator analogy as one in which the evaluation instrument also remedies skill deficits. Political polarization and radicalization have become societal concerns while internet use has become widespread. Many seek validation rather than information, reinforcing their views rather than new opinions or data.

Treatment of Pathologic Internet Use

Online therapy or anything else online cannot deal adequately with an addiction to being online. Remedying flight from the real world for whatever reason must involve reinvolvement in the real world, including the experience of treatment, as described as follows.

Breaks from the internet are recommended as a public health mechanism, including checking one's email only a few times/day.

Uses of HIT. Physicians will have to adjust to having dynamic medical records that tap automatically into various scientific databases. Clinical decision support is available in real time as decisions are made, not in the form of excessive warnings that guidelines are being violated, but in a positive, efficient, and supportive way. Many time-consuming transactions are performed automatically. Safety and quality can be achieved with EMRs, but cost savings depend on EHRs. Research to date shows costs increasing in the United States due to EHR use. Smart cards, presently used in France and Taiwan, offer a technology that transmits data as a service is given, records the service, and updates the patient EHR. However, these systems do without RHIOs and HIEs. The record is accessible only when a patient is seen and has put the smart card in the physician's card reader. Public health and public policy will be much better informed by having almost instantaneous aggregate patient-deidentified data on patient care.

Privacy and Security. HIT proponents argue that some sacrifices must be made for the common good of informing policy, public health, and research, whereas privacy advocates argue that patients should give affirmative consent to sharing every piece of personal data. It is unclear how much these opposing views will conflict in specific cases or how conflicts will be resolved. The rejection of British government proposals by an overwhelming majority of primary care physicians and their patients suggests that HIT proponents can become overly enthusiastic and lose a sense of public preferences. Only competent auditing can help to reduce the fraud that consumes about 10% to 15% of American health care costs. It is unclear whether clinician organizations will accomplish this or leave it to the insurers with whom there is already a power struggle.

"Privacy is over," runs one argument in the debate, while others argue it can be maintained. The reality is that different data matter more or less to different people. For example, some will post their entire genomes but not access their bank accounts.

Development of an Interconnected Information Society. Extracorporeal processing has created a new culture with alternate realities and identities, affecting communication, the problems patients bring to psychiatrists, and what psychiatrists can do for them. A generation that has grown up with microprocessors and the internet has incorporated them into their way of life. They use all manner of devices with ease and comfort and are driven to take up new ones. They are more concerned with communication than privacy and spend much time in touch with each other. Indicators of time spent sitting indoors show that Americans are spending less time outdoors and are facing an epidemic of obesity. The prevailing cultural model of for-profit medical care has eroded privacy in favor of marketing. Every patient can be viewed as a potential customer. Others outside the for-profit world offer a top-down consensus that many problems in U.S. health care can be eased through the use of EHRs, especially electronic prescribing programs that check for safety against other medications and patient data. Although such efforts have sputtered in the past, the current drive generally benefits from the continuing price decline and quality improvement of electronics and better planning, funding, and standard setting.

Revelations in October 2021 that social media, especially Facebook and Twitter (X), contribute to polarization, divisiveness, anxiety, depression, misinformation, and disinformation have led to theories about how best to achieve a more harmonious interconnected society. In India, the news feed has been especially problematic (https://www.washingtonpost.com/technology/2021/10/24/india-facebook-misinformation-hate-speech/).

HIT and Health Care Change. So far, HIT use has not brought the transparency and public policy consensus required for health care reform. Before agreeing on HIT, all sides agreed that costs were high, primary care doctors were underpaid, and all citizens should have medical bills covered. However, these three and other viability indicators have worsened despite intense fact-finding and discussion. The United States has allowed health insurance profiteering, which is regarded elsewhere as being the result of having a market rather than a coherent system. Pay-for-performance programs have been initiated, offering small bonuses compared to other countries. It is essential not to make promises for HIT that will lead to disappointment. However, the extreme portability of electronic records and the global reach of telemedicine may result in an outsourcing competition that will raise a host of issues.

Possible Therapeutic Uses of Games. While internet gaming can be so intense and time-consuming as to be on the threshold of being a treatable diagnosis, some studies have shown that playing computer games is therapeutic. Test instruments, such as the Wisconsin Card Sorting test, have been turned into games, with the idea that repeated use will improve performance—an example of the assessment test becoming the rehabilitation tool. Unfortunately, results have been mixed and somewhat disappointing. However, games can be linked to neural circuitry improvements (as was shown for alcoholism in 2015 by Weirs et al.). This study shows an interaction of internal, biologic processing circuits synchronizing with external, silicon-based circuitry.

Techniques

Becoming adept in using electronic devices is eased by the awareness that some cognitive and communication functions can be delegated to microprocessors and the internet. Formerly, information was hard to obtain; now, the problem is sifting through too much of it. Former Czech President Václav Havel posed the new problem as knowing more but being less wise. Clinicians should always be aware that people using electronic media make choices in the use of words and images, often involving an individual sense of self, effectiveness, and identity that may or may not be clinically significant. Clinicians should also choose consciously what data not to capture. For example, HIPAA protects psychotherapy notes, but emails and telepsychiatry sessions may mix material entitled to such protection with other data for which less sequestration is possible. The use of electronic media is not a new form of therapy but a different way of carrying out a variety of therapies, some of which lend themselves better than others to the use of electronic media. First, however, there are some general considerations, which are described as follows.

RESEARCH AND EVALUATION

There is little funding for research on electronic media. Government and professional associations have decided to favor use, as described earlier. Equipment manufacturers are preoccupied with producing new models for the general population and remaining price competitive. There is no special equipment for anything described here. EMR vendors sponsor exhibits with little research, but government and the American Medical Records Institute provide some funding.

Problematic Internet Use

In a telephone survey of 2,513 adults, 69% were regular internet users, 6% felt that their relationships suffered as a result of excessive internet use, and 8% used the internet as a way to escape problems or relieve negative mood. Other potential markers for problematic use included preoccupation with offline internet, concealing nonessential use, failed attempts to cut back use, and frequently using the internet longer than intended. Interviews of 216 college students in Taiwan found 87 internet addicts, with associated major depressive disorder (MDD), ADHD, dysthymic disorder, and social phobia, with most addicts being male students with MDD or ADHD. Only seven men and eight women had no comorbidity.

Telepsychiatry

Twenty-eight inmates of New York prisons receiving services from their on-site treatment team and from visiting consultants in person or via telepsychiatry preferred the former for most services. None preferred telepsychiatry to face-to-face communication, but telepsychiatry was accepted and tolerated, especially for contact with experts who would not come into the prison. Diagnostic reliability using the Structured Clinical Interview for DSM Disorders (SCID) in 53 Native American veterans was comparable in person and with telepsychiatry except for past-year substance use and abuse/dependence combined. Telepsychiatric consultations and brief follow-up were rated as producing outcomes equivalent to face-to-face communication in 495 Canadian patients referred by family physicians, with a 10% cost saving. A comparative study of 119 U.S. veterans found no differences in outcome, patient satisfaction and adherence, and cost. Other studies have generated controversies about costs in rural areas. Video feedback is helpful in several studies in which it was used in the context of an ongoing face-to-face relationship.

There are no comparisons between online therapy and face-to-face communication because it is generally accepted that the former excludes body language, facial expressions, eye movement observation, tone of voice, and others. Studies confirm the commonsense view that evaluative feedback (not in therapy) is given more effectively in face-to-face encounters than by computer. Anecdotal evidence supports the widespread view that online availability and email contact can be helpful between meetings in therapeutic sessions.

Published reports on telemedicine are generally brief, emphasizing how to do it and minimizing any differences between the telemedicine experience and face-to-face communication. Evaluative data describe satisfied patients and savings on travel time and costs. Although it is understood that some data are excluded, there has been no systematic investigation of how missing data can influence the outcome. Despite more than five decades of use, a Cochrane review in 2010 (http://www.cochrane.org/CD002098/EPOC_telemedicine-versus-face-to-face-patient-care-effects-on-professional-practice-and-health-care-outcomes) comparing telemedicine with face-to-face communication found only variable and inconclusive results. Subsequent reviews have shown benefits in specific areas such as health monitoring of high-risk patients.

As with most forms of therapy and new treatments, there have been phases of zealotry, exaggeration of possible benefits, some disillusionment, and loss of interest. Annual meeting programs of the American Psychiatric Association, American Psychological Association, and World Psychiatric Association show decreasing reports on the use of electronic media from a peak in 1999, increasing during the pandemic, and less reporting as telepsychiatry and electronic communication are accepted as facts of everyday life. Those who pay for public and private care have adopted the fundamental decision to use more telepsychiatry. In addition to reimbursement through Medicare and Medicaid, the Office for the Advancement of Telehealth of the Health Resources and Services Administration (part of the Department of Health and Human Services), among many funding sources, provides grants and contracts and publishes a directory of supported projects. The WHO promotes telemedicine annually in its regional advisory committee meetings, especially for developing countries. The growth in teleconferencing reflects the evaluation of those who pay for it. Rather than comparisons with face-to-face meetings, telepsychiatry should be compared to no or inexpert service. The Journal of Telemedicine and Telecare (http://jtt.sagepub.com) was started in 1995 and is published monthly. It mainly describes the extension of telemedicine into remote settings and its use in various diagnoses, such as dementia. It includes papers on information infrastructure and the situation in developing countries but no controlled studies.

Virtual Reality Therapy. VRT has been evaluated positively versus standard desensitization for phobias, especially fear of flying, using standard outcome measures. Wiederhold and Wiederhold summarized numerous positive studies. However, no studies demonstrate its superiority, although it is likely that clinicians who invest in the equipment and master the technique will eventually attract patients who have not improved with standard desensitization. A few studies dealing with other diagnoses such as schizophrenia, body image distortion, and eating disorders include new diagnostic methodologies and showed positive outcomes persisting for up to 1 year after treatment.

Electronic Medical/Health Records. Studies of EMRs and EHRs have described the use of databases to get accurate information about patients (e.g., arrests, medications, diagnoses), including refusals and concerns (among those agreeing) of patients to have their paper records entered into electronic media. In general medicine, physicians report a decline in productivity while adapting to EMRs, followed by practicing medicine differently with higher quality and safety and noticing a decline in paperwork and wasted communication time. Only 10% of physicians using electronic records abandon them to return to paper records. Many reports of electronic records are being harvested for previously uneconomic investigations (e.g., substance abuse–related mortality in 169,051 veterans over 7 years).

In Boston, a cardiologist at Massachusetts General Hospital described their frustration on Twitter (X): “Why are nearly all notes in Epic … basically ‘useless’ to understand what’s happening to a patient during a hospital course?” Another doctor’s reply says, “Because notes are used to bill, determine the level of service, and document it rather than their intended purpose, which was to convey our observations, assessment, and plan. Our important work has been co-opted by billing.”

The promise of bringing medical record keeping into the digital age was to maintain a live record of a live patient, enabling clinicians to track patient care across hospital systems and over time. Instead, we have been saddled with systems that cut into patient care (clinicians typically spend an hour feeding documentation for every hour they spend with patients) and, often, are too fragmented to allow a patient's file to follow her from one medical center to another. The EMR, as a colleague of mine put it, is "electronic in the same way your grandfather's radio is electronic." The energized, improvisatory role of medical Twitter (X) inevitably draws attention to what our bulky, billion-dollar systems should have been providing—to the cost, in dollars and lives, of the rapid clinical learning that we have foregone.

It is hardly news that our EMR systems have failed medicine. However, an executive order from New York State, issued at the end of March by Governor Andrew Cuomo, amounted to a grim epitaph: "Health care providers are relieved of record keeping requirements to the extent necessary for health care providers to perform tasks as may be necessary to respond to the COVID-19 outbreak … Any person acting reasonably and in good faith under this provision shall be afforded absolute immunity from liability. A system designed to expedite and improve the delivery of health care was officially recognized as an obstacle."

7.10 Cultural Competency in the Organization and Delivery of Psychiatric Care

CAROLE E. SIEGEL, PH.D., HELENA B. HANSEN, M.D., PH.D., AND JONATHAN MICHEL METZL, M.D., PH.D.

Cultural competency (CC) is a notion borne from considerations of nondiscrimination that has been applied in various contexts, including national and international affairs, education, the workplace, and health care. In all these venues, it speaks of productive ways to achieve equitable ends in situations where a mainstream or majority group–sometimes a power group–interacts with “other” cultural groups–usually minority or possibly disadvantaged groups–who have values and views and sometimes languages that are appreciably distinct from the “mainstream.” The specific contextual issues and the positions taken can substantially differ from venue to venue. For example, while debates can ensue as to whether or not immigrant children in the United States should be educated in their native languages and in specially designed educational courses, there is no analogous debate in health care. In the United States, Western medicine is predominantly delivered in English, but there is wide agreement that language accommodations are required for persons from cultural groups who have limited English proficiency.

Since 2014, several events of notoriety have occurred in which law enforcement agents were involved in adverse community situations, and Black lives were lost. A collective response to this which has had a substantial national impact is the “Black Lives Matter” movement which aims to eliminate the occurrence of such events and to raise public awareness of innate biases in the population and prejudicial treatment of Blacks, as these factors may have played contributory roles. Organizations both private and public used by diverse groups, including educational and medical settings, have responded and actively put in place activities to ensure that their settings are open and respectful of its diverse community members. At NYU Langone Hospital, an Office of Diversity Affairs was established within which activities to fulfill the goals of diversity and inclusion were put in place. There is a roadmap and timeline for promoting an inclusive and equitable culture of medicine. This includes hiring and placement at all institutional levels and particularly in leadership positions, a diverse faculty and staff, as well as the establishment of a greater array of diversity training activities in the School of Medicine. Medical education now includes a curriculum on systemic racism and its impact on health outcomes. Many of the activities that have been suggested are the same as those endorsed under organizational CC that aim to accommodate diversity and promote equitable care.

Here, we explicate the notion of CC, providing background on mental health disparities, some formal government responses through the years, and some proposed solutions for organizations, their programs, and their staff to improve their CC in the delivery of care. In part II, structural competency is introduced, which addresses the societal influences and social determinants of health that can cause disparities in treatment and care outcomes. Specific recommendations for clinical care that integrate social awareness of these factors are exposited.

Suggestions are made to move the discussion of CC in health care–with a focus on mental health care–beyond a rehearsal of compliance issues and the rhetoric of political correctness to a description and justification of the CC activities that can be used to promote patient-centered care. While it is critical to apply these activities in all health areas, it is particularly crucial in mental health care, where diagnoses are made and many treatments delivered strictly based on verbal communication. Operationalizing the activities of CC has remained challenging, but the landscape of the ‘80s, when these notions were first introduced, has considerably changed based on the broad recognition that for CC to move forward, greater specificity was required on how to do this. Recent societal events of negative import reinforce the need to have specific activities in place that will have an impact.

DEFINITIONS: CULTURAL GROUP; CULTURAL COMPETENCY

A cultural group has shared activities, ideas, and traditions, which are reinforced by its members. The group is a dynamic entity as the views and values of its members can change over time and are influenced by where people live as well. Thus Chinese and Chinese American cultures in 2014 differ from each other, and each group differs from itself pre- and post-Chinese economic reforms. Federal policies for health care to date have been framed to ensure nondiscrimination only for minority racial/ethnic groups, but CC is intended to apply to any cultural group that encounters limitations in service access or in participation in services. While clearly including underserved racial/ethnic groups, it also encompasses groups disadvantaged in health care such as lesbian, gay, bisexual, and transgendered communities, the born Deaf, and even rural communities, each having distinct lifestyles. Anthropologists have recently questioned the value of culture in understanding a persons' behaviors, as monolithic constructs fail to account for variations in expression and experiences within cultures. The notion of a cultural identity attempts to address this deficit by recognizing that persons belong to multiple cultural groups, and the intersectionality of these groups is what shapes a worldview. Cultural groups are defined by more than race, ethnicity, country of origin and go beyond to encompass socially defined groups for which membership impacts daily living, such as groups defined by socioeconomic status, professional roles, gender, and stage of life roles. Thus a Black, unmarried, inner-city male will differ in world view from a Black father who lives in suburbia. CC training materials for clinicians take cognizance that persons' views of their cultural identity are fundamental to understanding how they make sense of the world and hence how they respond to and interact with a health care provider.

Many definitions of CC in health care have been proposed, of which the most commonly cited in mental health care is that of Terry Cross. He defines CC as "a set of congruent behaviors, attitudes, and policies that come together in a system, agency, or among professionals and enables that system, agency, or those professionals to work effectively in crosscultural situations." This definition first appeared in a monograph on ways to work with severely and emotionally disturbed minority youth written for the Georgetown University Child Development Center (now the National Center for Cultural Competency), an early promoter of CC in the delivery of children's services. A less proscriptive definition defines Cultural Competence in an individual or organization as having the capacity to function effectively within the context of the cultural beliefs, behaviors, and needs presented by consumers and their communities. While these definitions are all-encompassing, to better understand their implications, it is helpful to parse them into the distinct ways they apply to organizations and to caregivers.

When considering healthcare organizations that broadly include structural entities such as departments of mental health, managed care companies, hospitals, agencies, and programs, CC is referential to the policies and procedures that should be endorsed and promoted throughout an organization to enable caregivers and other staff under the purview of the organization to work effectively and efficiently with different cultures and within multicultural situations to provide high-quality services. On the clinical level, CC refers to the desirable personal attributes of clinicians encompassing their attitudes (affective domain), knowledge (cognitive domain), skills, and actions (behavioral domain) that enable them to work effectively and efficiently across cultures and in multicultural situations to produce clinically and culturally appropriate service outcomes. This latter definition addresses clinician values, overt and covert biases, as well as the knowledge and skills guiding the ways to act. There has been notable clinical resistance to the concept of CC as many believe that it is already addressed or implied in clinical competency or feel it is already adequately addressed when a clinically competent clinician practices patient-centered care. The Institute of Medicine defines clinical competency as the ability to use clinical skills and knowledge to identify each consumer's unique health state and diagnosis, individual risks and benefits of potential interventions, and personal values and expectations. In working with persons with severe mental illness, some curricula endorse core competencies to address recovery, rehabilitation, and empowerment. The argument goes, if these notions are fully operant, CC will be embedded in clinical competency. But for now, CC is not treated as a distinct construct in clinical training or adequately represented in its curriculum, so that CC needs to be viewed as a distinct competency.

It is well documented that clinicians' misunderstandings of cultural sensibilities can lead to failed treatment alliances. Many psychiatric training programs around the country have instituted CC didactics and curriculum that explicate one or more of the attributes of CC identified by Derald Sue and others of attitudes, knowledge, and skills. For example, the New York University psychiatric CC curriculum has included three modules, two of which address attitudes (and awareness): Perceiving the Other and Perceiving Self. In the former, residents learn how sociocultural influences impact clinical presentations, and in the latter, residents experience their own cultural backgrounds and examine their influence on the doctor–patient relationship. Action skills are taught through a third practicum module where residents practice conceptualizing culture in the doctor–patient encounter using a culturally interpretive clinical approach. Other models have been proposed for guiding clinical competency, and one such other is discussed later.

STRUCTURAL COMPETENCY: ADDRESSING INSTITUTIONAL DRIVERS OF INEQUALITY

Jonathan Metzl and Helena Hansen have introduced a construct called structural competency that addresses the institutional and policy-level (i.e., structural) drivers of disparities in treatment and health outcomes. These drivers shape the social determinants of mental health in populations, as well as mental health care delivery systems and the practice environments of clinicians who deliver care. The premise of structural competency is that health inequity results from and reflects institutionally embedded inequalities, including systemic racism, that sicken marginalized groups of people through such social determinants as unstable housing, unsafe polluted neighborhoods, lack of access to fresh food, unemployment, substandard education and high levels of police surveillance and incarceration. Clinical practitioners are traditionally trained in individual patient-level interventions, but as health experts they can, when taught the relevant skills, work with institutional stakeholders to reorient policies and practices toward health promotion. Clinical practitioners are in a privileged position not only to redesign clinical services to address structural barriers to care (such as by providing transportation and social services) but also to collaborate with community organizations, nonhealth sector agencies such as housing assistance, education, and legal aid, as well as policymakers, to promote health through community-based programs. Structural competency frameworks also emphasize the mental health effects of particular health policies, and increasingly clinicians can help to develop and implement policy solutions to some of the most pressing social and political issues of our time, including gun violence and mass incarceration.

A growing number of medical schools are developing structural competency curricula and community practicums (see structuralcompetency.org). They provide classroom and community-engaged experiential learning based on three fundamental principles: (1) understanding patients' experiences in terms of their structural drivers; (2) intervening to address those drivers at institutional levels (through community organizations, nonhealth agencies, and public policy); and (3) practicing structural humility, which means seeking out multidisciplinary collaborators with other types of expertise, including community organizing, and having patience with the slow pace of structural change. Some psychiatry residency programs have worked with faculty members who are social scientists and community organizers to create structural competency trainings that specifically address barriers mental health.

FIGURE 7.10–1. Hierarchical levels of health care system.

Figure 7.10–1 displays the hierarchical levels of a health care system in which CC activities need to be introduced. Structural competency is added as a meta-level to the Terry Cross view of CC as structural competency impacts operations and behaviors at all of the displayed levels.

WHY CC IS IMPORTANT: DIVERSITY, DISPARITIES

The Percent non-White of the U.S. Population is Growing

According to the most recently published U.S. Census figures (2021), 40.7% of the U.S. population is non-White. 18.9% report themselves as Hispanic/Latino, 12.6% as Black/African American, and 5.9% as Asian. The Hispanic/Latino group in the United States is even larger as many in this group have entered the country as illegal immigrants and are not counted officially in any of the U.S. Census counts. Nevertheless, many of these persons will avail themselves of emergency rooms in hospitals and use hospital clinics when confronted with mental health problems. Racial/ethnic groups that require special attention from psychiatric practitioners comprise an ever-increasing proportion of all persons served. For example, in NYS in its public mental health system (which excludes private practice practitioners), in 2013, 24.3% were Black, non-Hispanic, 23.3% were Hispanics, and 1.9% were Asian American.

Continuing Evidence of Disparities

In 1978, the first report of the President's Commission on Mental Health explicitly recognized critical disparities among racial and ethnic minorities. President Jimmy Carter and especially his wife Rosalynn became strong advocates for rectifying these disparities. A series of reports originating with the Western Interstate Commission on Higher Education commissioned by the Substance Abuse and Mental Health Services Administration focused on the four broadly defined racial/ethnic groups identified as underserved and underrepresented in managed mental health care—**Americans of African Descent, Asian and Pacific Islanders, Latinos, and Native American Populations—and compiled into a comprehensive volume a great depth and breadth of knowledge about the mental health needs of these cultural groups.** The Surgeon General's 2001 Supplemental Report reported on the mental health care of these major underserved racial/ethnic groups finding disparities in availability and access to needed services. The report endorsed CC in care delivery as a key approach for the reduction of these disparities, although there was no elaboration on how to do this.

There is strong evidence of sustained disparities in mental health. Researchers continue to find disparities for racial/ethnic minority groups in service accessibility, service utilization, as well as inpatient satisfaction. Asians remain less likely to access care than other groups. There are also still notable disparities in the reported prevalence of mental health conditions among groups, with reasons for this at best only speculative. Several authors have linked prevalence differences to a misunderstanding of cultural presentations of symptoms resulting in both over and underdiagnoses. Papers still speculate on reasons for higher rates of diagnoses of psychosis in Black adults, ADHD in Black children, and lower rates of diagnoses of depression in Latinos. Mechanisms of disparities are often linked to social determinants, for example, poverty, and to structural factors such as federal and economic health policy, operations of the health care system, provider factors, and environmental contexts. Residential segregation of services and providers and provider shortages may also account for access and use disparities. For example, for Native Americans, in 2018, it was noted that the Indian Health Service (HIS) remains understaffed and underfunded. A review of disparities across the country based on some recent studies conducted from 2010 to 2015 is presented in Table 7.10–1.

While it is hard to evaluate whether disparity rates have been increasing or decreasing over time, an effort has gone into producing services likely to eliminate disparities for cultural groups. This includes culturally adapted assessment instruments, norming these instruments for racial/ethnic groups and training psychiatrists on how to make more culturally sensitive diagnoses, adapting evidence-based services to better fit the styles and mores of cultural groups, and introducing alternate services more acceptable to certain cultures, such as those that incorporate religion and spirituality into a therapeutic approach. A recent effort to increase the success of therapeutic alliances between persons with disorders and their therapists directly encourages peers to present to their caregivers the aspects of their cultural identity that can influence their receptivity and the success of the care they are being prescribed. It is described below.

CULTURAL AWARENESS OF CAREGIVERS

Growing Recognition of the Role of Cultural Competency in Care Delivery

Some authors locate the roots of a concern with cultural awareness in clinical training in the 1950s to 1960s postwar social sciences. A group of medical sociologists and anthropologists, Talcott Parsons among them, studied the professional acculturation and socialization of doctors during clinical training. What had been taken for granted as primarily technical education was revealed to be a rich cultural milieu, replete with rituals, key symbols, rites of initiation, and social dramas, which led researchers and clinicians to a growing awareness of the “culture of medicine” as opposed to the culture of patients. There is a consensus, however, that the term “cultural competence” was not widely used in medical journals or clinical training until the 1980s when the Association of American Medical Colleges and the Accreditation Council of Graduate Medical Education called upon medical schools and residency programs to train clinicians to address their patients’ “culture,” which largely referred to their patients’ ethnic and racial identity. The term “cultural competency” and the concern with outcome disparities came from the field of education, which had used the term with regard to addressing educational attainment disparities by ethnicity and race.

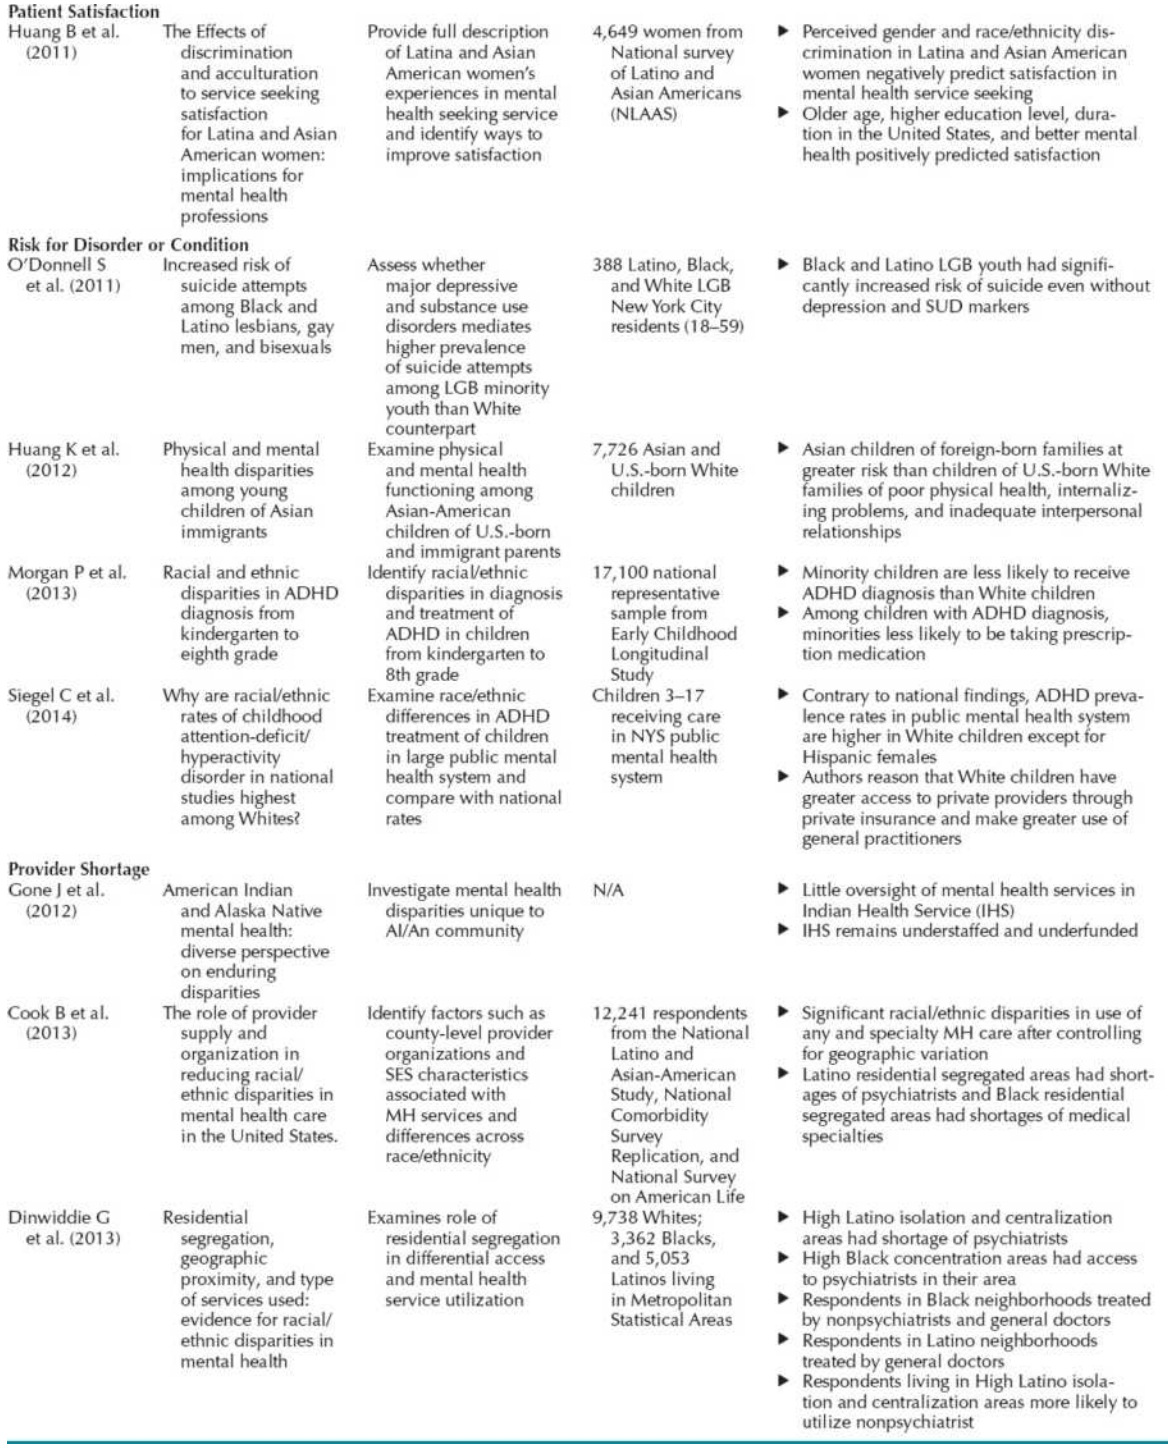
In psychiatry, this awareness of cultural differences between practitioners and patients as relevant to clinical practice was codified in the DSM IV, published in 1999. Psychiatrist-anthropologist Arthur Kleinman led a special committee of the DSM IV Task Force devoted to cross-cultural psychiatry that introduced new diagnostic frames and clinical tools to the DSM IV appendix. These included “culture-bound syndromes” and the Cultural Formulation, a guide to interviewing and diagnosing patients using questions that took the patients’ cultural understanding of their problem into account, using Kleinman’s Explanatory Model. This contrasted with the symptom checklists of the DSM III, which had aspired to use universally applicable symptom descriptions, descriptions that soon proved to be interpreted differently across ethnic and language groups, and which some practitioners argued led to misdiagnosis. At about the same time, Derald and Stanley Sue were advocating for the cultural competence of clinicians, particularly in their work in counseling and psychotherapy. They emphasized the need for a greater understanding of psychiatric symptoms that could be misunderstood across the cultural divide between Western medicine and Chinese patients. They emphasized the need for addressing cultural beliefs, attitudes, knowledge, and skills and developing new counseling competency standards when working with multicultural populations.

By 2000, as the DSM IV Cultural Formulation gained visibility, and as increasing numbers of medical schools adopted some form of training in cross-cultural patient care, competing models of training in cultural issues emerged. The first might be called cultural expertise, in reference to the goal of having medical trainees gain knowledge of the beliefs and behaviors of their patients' cultural groups. In practical terms, this led medical schools to emphasize language translation services and, in some cases, "cultural consultants" who are members of minority ethnic groups employed by medical centers to assist healthcare providers in communicating with their patients. The second approach might be called cultural sensitivity, in which the goal is not to master bodies of knowledge about the cultural groups from which patients come, but rather to understand the broader psychosocial context of each patient, to ask each patient's guidance in learning what is relevant to them, and to heighten the cultural self-awareness of clinical practitioners so that they can take their own biases into account in their exchanges with patients. These two approaches, cultural expertise and cultural sensitivity, are not mutually exclusive, but many medical training programs emphasize only one.

Expanding on the cultural sensitivity approach, the term "Cultural Humility" was introduced by pediatricians, who offered "humility" instead of "competency" because it conveys the attitude a doctor would need to adopt in order to learn from the unique circumstances and thinking of each patient. The practical elements they proposed were (1) self-evaluation of the health care provider to root out cultural assumptions that might reinforce their stereotypes of and discrimination against patients, (2) empowering patients to have a voice in their own decision making; and (3) forming partnerships with communities to advocate for more locally responsive health care.

Table 7.10–1.
Selected Disparity Literature Review: 2010 to 2014

Authors (year)	Title	Objective	Sample	Conclusion
Service Accessibility and Utilization				
Wu P et al. (2010)	Mental health service use among suicidal adolescents: findings from a U.S. National Community Survey	Assess patterns of mental health service use among adolescents who had attempted suicide and examine service at individual and community level	877 adolescents (12–17) who attempted suicide in the past 12 months	▶ Mental health needs of minority, lower-income families are unmet ▶ Larger race/ethnic disparities in use of in and outpatient services than in school-based services ▶ School-based services more accessible to suicidal adolescents who may experience barriers in receiving standard care
Alegria M et al. (2011)	Disparities in treatment for substance use disorders (SUD) and co-occurring disorders for ethnic/racial minority youth	Review literature on racial/ethnic disparities, focusing on SUD services and comorbid behavioral health disorders in children and adolescents	N/A	▶ Compared with non-Hispanic-Whites, Black adolescents with SUD reported receiving less specialty and informal care ▶ Latinos reported receiving less informal care ▶ Mechanisms of disparities identified in federal and economic health policy, operations of health care system, provider factors, environmental context, patient factors, etc.
Cummings J et al. (2011)	Racial/Ethnic differences in mental health services use among adolescents with major depression	Examines difference in mental health services use in NH-Whites, Black, Hispanic and Asian adolescents experiencing major depression	7,704 adolescents (12–17) with major depression in past year–nationally representative	▶ Black Hispanic and Asian adolescents significantly less likely than non-Hispanic Whites to receive prescriptions medication, to receive treatment for depression from specialist or provider, and receive outpatient treatment, after adjusting for family income and insurance status
Akincigil et al. (2012)	Racial and ethnic disparities in depression care in community-dwelling older adults in the United States	Investigated racial/ethnic disparities in diagnosis and treatment among community-dwelling older adults	Medicare Current Beneficiary Survey, n = 33,708	▶ Blacks significantly less likely than non-Hispanic Whites to receive depression diagnosis from provider and if diagnosed less likely to be treated
Cook B et al. (2013)	Assessing racial/ethnic disparities in treatment across episodes of mental health care	Investigating race and ethnic disparities in decisions to start and terminate care and decisions during treatment	Whites, Blacks, and Latinos with probable mental illness	▶ Blacks and Latinos initiated care less frequently ▶ Black and Latino episodes were shorter ▶ Black and Latino had fewer psychotropic drug fills
Kim G et al. (2011)	Limited English proficiency (LEP) as a barrier to mental health service use: a study of Latino and Asian immigrants with psychiatric disorders	Examine the effect of LEP on mental health service among immigrant Latino and Asian adults with psychiatric disorders	372 immigrant adults (18–86) with any instrument-determined mood, anxiety, and SUD	▶ LEP of Latinos but not of Asians significantly reduced odds of mental health service use ▶ Asians less likely to access care
Jimenez D et al. (2012)	Disparities in mental health service use of racial and ethnic minority older adults	Apply the IOM definition of health disparities, to measure disparities in different episodes of mental health care	1,658 adults >60 with likely mental health care need	▶ Treatment initiation is significantly lower and the adequacy of treatment is significantly poorer for Black and Latino older adults than White counterparts ▶ Latinos had significantly longer treatment duration, more visits, and higher expenditures
Merikangas K et al. (2012)	Service utilization for lifetime mental disorders in U.S. adolescents: results of the National Comorbidity Survey–Adolescent Supplement (NCS-A)	Examine rates and sociodemographic correlates of lifetime mental health service use by severity, type, and number of mental health disorders	6,483 nationally representative adolescents (13–18)	▶ Black and Non-Hispanic Black were less likely to receive mood and anxiety disorder services than White counterparts
Siegel C et al. (2013)	Access to and use of noninpatient services in New York state among racial-ethnic groups	Report on differences in use of noninpatient services in Hispanics, Asians, and non-Hispanic Blacks and Whites using NYS public mental health system	NYS OMH 2009 Patient Characteristic Survey	▶ Higher treated prevalence for Latinos and Blacks compared to Whites ▶ Lower prevalence rates for Asians ▶ Lower treatment intensity among Black youth with disruptive disorders, Hispanic adults with anxiety, and Asians <65 with depression compared to White counterparts ▶ In upstate metropolitan areas, Black youth and Hispanic adults had lower treatment intensity than Whites ▶ In NYC, Whites >65 had higher treatment intensity than other groups



Patient Satisfaction				
Huang B et al. (2011)	The Effects of discrimination and acculturation to service seeking satisfaction for Latina and Asian American women: implications for mental health professions	Provide full description of Latina and Asian American women's experiences in mental health seeking service and identify ways to improve satisfaction	4,649 women from National survey of Latino and Asian Americans (NLAAS)	▶ Perceived gender and race/ethnicity discrimination in Latina and Asian American women negatively predict satisfaction in mental health service seeking ▶ Older age, higher education level, duration in the United States, and better mental health positively predicted satisfaction
Risk for Disorder or Condition				
O'Donnell S et al. (2011)	Increased risk of suicide attempts among Black and Latino lesbians, gay men, and bisexuals	Assess whether major depressive and substance use disorders mediates higher prevalence of suicide attempts among LGB minority youth than White counterpart	388 Latino, Black, and White LGB New York City residents (18–59)	▶ Black and Latino LGB youth had significantly increased risk of suicide even without depression and SUD markers
Huang K et al. (2012)	Physical and mental health disparities among young children of Asian immigrants	Examine physical and mental health functioning among Asian-American children of U.S.-born and immigrant parents	7,726 Asian and U.S.-born White children	▶ Asian children of foreign-born families at greater risk than children of U.S.-born White families of poor physical health, internalizing problems, and inadequate interpersonal relationships
Morgan P et al. (2013)	Racial and ethnic disparities in ADHD diagnosis from kindergarten to eighth grade	Identify racial/ethnic disparities in diagnosis and treatment of ADHD in children from kindergarten to 8th grade	17,100 national representative sample from Early Childhood Longitudinal Study	▶ Minority children are less likely to receive ADHD diagnosis than White children ▶ Among children with ADHD diagnosis, minorities less likely to be taking prescription medication
Siegel C et al. (2014)	Why are racial/ethnic rates of childhood attention-deficit/hyperactivity disorder in national studies highest among Whites?	Examine race/ethnic differences in ADHD treatment of children in large public mental health system and compare with national rates	Children 3–17 receiving care in NYS public mental health system	▶ Contrary to national findings, ADHD prevalence rates in public mental health system are higher in White children except for Hispanic females ▶ Authors reason that White children have greater access to private providers through private insurance and make greater use of general practitioners
Provider Shortage				
Gone J et al. (2012)	American Indian and Alaska Native mental health: diverse perspective on enduring disparities	Investigate mental health disparities unique to AI/An community	N/A	▶ Little oversight of mental health services in Indian Health Service (IHS) ▶ IHS remains understaffed and underfunded
Cook B et al. (2013)	The role of provider supply and organization in reducing racial/ethnic disparities in mental health care in the United States.	Identify factors such as county-level provider organizations and SES characteristics associated with MH services and differences across race/ethnicity	12,241 respondents from the National Latino and Asian-American Study, National Comorbidity Survey Replication, and National Survey on American Life	▶ Significant racial/ethnic disparities in use of any and specialty MH care after controlling for geographic variation ▶ Latino residential segregated areas had shortages of psychiatrists and Black residential segregated areas had shortages of medical specialties
Dinwiddie G et al. (2013)	Residential segregation, geographic proximity, and type of services used: evidence for racial/ethnic disparities in mental health	Examines role of residential segregation in differential access and mental health service utilization	9,738 Whites; 3,362 Blacks, and 5,053 Latinos living in Metropolitan Statistical Areas	▶ High Latino isolation and centralization areas had shortage of psychiatrists ▶ High Black concentration areas had access to psychiatrists in their area ▶ Respondents in Black neighborhoods treated by nonpsychiatrists and general doctors ▶ Respondents in Latino neighborhoods treated by general doctors ▶ Respondents living in High Latino isolation and centralization areas more likely to utilize nonpsychiatrist

Another expansion on the idea of provider self-evaluation was introduced by psychiatrist-social scientists Elizabeth Bromley and Joel Breslow in an approach to clinical education that develops "Critical Thinking Skills." They propose heightening trainees' self-awareness of the culture of medicine by teaching them the history of medicine and sociocultural research on medicine. They argue that this prepares trainees for leadership in medicine through understanding their own role in the larger institutions that are constraining patients' care and options. For example, trainees learn from this material that the U.S. health care system locates disease in the individual, rather than the community or the environment, which explains its focus on "compliance/adherence" rather than on the patient's milieu, their resources, and supports. Another example, clinicians are trained to tell diabetics to limit their intake of sugar and processed foods, but not to ask if they live near grocery stores with fresh foods or if they know how to cook.

Cultural Activation of Consumers to Provide Cultural Information to Their Caregivers

Carole Siegel, Lenora Reid-Rose, and Gary Haugland have posited that since the health activation of consumers has been documented to improve health outcomes, "cultural activation" of consumers might do so as well. Cultural activation was framed as a consumer's recognition of the importance of providing cultural information to providers about their cultural affiliations, challenges to receiving care, views about and attitudes toward behavioral health and general medical health care, and the ability to transmit such information. In conjunction with several consumer groups, they developed prompts for consumers to use to help them culturally represent themselves, thus promoting shared decision making as part of the therapeutic alliance and acting as a form of consumer empowerment (Table 7.10–2).

The prompts help consumers transmit to providers cultural information about their identities, their views of their mental health challenges, and the supports and barriers that they may encounter. They draw on the domains covered in the *DSM-5* Cultural Formulation Interview and on the "three C's" of Kleinman's explanatory model of illness: call, cause, and course. YouTube videos made by the Substance Abuse Mental Health Administration, are available that explain and support the use of these prompts. It is not intended to replace the Cultural Formulation Interview but rather to serve as a portable aid for consumers to transmit culturally relevant information to caregivers whenever the consumer feels it is needed to do so.

GOVERNMENT RESPONSE: STANDARDS, REGULATIONS, AND LEGAL REQUIREMENTS

The civil rights movement of the sixties heightened concerns about discrimination in health care. Title VI of the Civil Rights Act of 1964 states that “no person in the United States shall, on the grounds of race, color or national origin, be excluded from participation in, be denied the benefits of, or be subjected to discrimination under any program or activity receiving Federal financial assistance.” A primary focus at the federal level has been to remove language barriers that can prevent access to both general and mental health care. The Americans with Disabilities Act of 1990 mandated accessibility to facilities and programs for persons with disabilities, and this included psychiatric conditions. It also provided an impetus for introducing principles of CC into federally funded mental health programs. In 2000, President Bill Clinton signed Executive Order 13166 “Improving Access to Services for Persons with Limited English Proficiency,” which requires federal agencies and those receiving federal funding to identify service needs of persons with LEP and implement systems to ensure persons have meaningful access to services without unduly burdening the mission of the agency. Guidance issued by the Department of Justice spells out compliance standards to be followed to ensure programs and activities provided in English are accessible to persons with LEP. Ensuring that language is no barrier to health care, this action addresses discrimination on the basis of national origin, which was prohibited by Title VI. In 2000, the U.S. Department of Health and Human Services, through the Office of Minority Health, published National Standards for Culturally and Linguistically Appropriate Services in Health Care referred to as the CLAS standards. However, while provisions for culturally competent care and administrative and organizational supports were encouraged, only the provisions for linguistic assistance were made a mandated requirement. Neither the metrics to measure compliance to these standards nor enforcement guidelines accompanied the standards, although these came at a later date. The CLAS standards were revised in 2013 and augmented with an extensive set of guidelines for an organization to employ these standards (see Table 7.10–3). The new CLAS standards are organized into overarching themes. Communication and language access; engagement, and continuous improvement and accountability encompass the original standards, and a new standard, governance, leadership, and workforce, is included to ensure that CLAS standards are integrated and implemented throughout an organization.

Table 7.10–2.
Cultural Activation Prompts for Consumers

Cultural Activation Prompt	Explanation
1. How would you like to be called 2. The kind of person you would feel good about getting care from 3. Your cultural identity 4. Any negative or traumatic experiences you have had because of your cultural identity.	These first prompts are suggested to be used when a consumer and provider first meet and get to know one another. These prompts help create the foundation of a respectful, honest, and open relationship. These set the stage for future conversations about cultural identity. They give providers a baseline understanding of how consumers view themselves from a cultural perspective. The fourth prompt can begin a discussion on how the consumers may have experienced events in relation to those outside their cultural identity groups.
5. The names you and people from your cultural groups give for why you are seeking care. 6. What you and people from your	Prompts 5–8 are also suggested to be used when a consumer and provider first meet and get to know one another. These prompts give consumers a way to articulate the importance of their cultural norms. Finally, they can begin a conversation to help clarify the nature of their challenges in a cultural context.

cultural groups think may be the cause(s) of your health challenges	
7. Why people from your cultural groups think you need care	
8. What people from your cultural groups feel about you seeking care	
9. Who from your cultural groups might help you while you are in care	Prompts 9–11 are suggested to be used when a care plan is being made. The prompts help consumers articulate their preferences from a strengths perspective. They can be used to identify social supports that may not typically be considered.
10. Kinds of different care you have had that were helpful	
11. Care that you have had that	

	was not helpful	
12.	Things you like to do where you live, worship, shop, socialize, etc. with people from your cultural groups	This final prompt is suggested to be used when planning for recovery in the community. This prompt helps identify activities that relate to their cultural identity that can help consumers maintain good outcomes while tapping on cultural community strengths. Additionally, it can begin or continue a conversation on building additional social supports in the community.

The CLAS standards have been tied to the review criteria of the Joint Commission (formerly Joint Commission Accreditation of Hospitals/Healthcare Organizations) for the accreditation of hospitals and other health care organizations that have been expanded to include more explicit cultural and linguistic elements. The Joint Commission is essentially the gatekeeper for hospitals to obtain federal funds for inpatient care and has focused its reviews on an organization’s safety and quality of care standards. Accreditation of hospitals and medical schools requires adherence to these standards. Additionally, the National Committee for Quality Assurance has standards for cultural competence that health care organizations and managed care plans must address as part of their accreditation process.

Some recent government-mandated changes in insurance coverage for health care and the way in which individual insurance plans pay for mental health services need to be considered to examine whether they have influenced the receipt of mental health care by racial/ethnic groups. The Affordable Care Act, passed in 2010, has been shown to have increased access to care for lower socioeconomic groups, which include many racial/ethnic persons most positively affecting those living in states in which there was an expansion for Medicaid recipients who could enroll because of more liberal criteria. Effects on outcome have not yet been well studied, particularly on racial/ethnic groups, and outcome evidence that exists is mixed to date, but access has been documented to have improved. The Mental Health Parity and Addiction Equity Act of 2008 require large-group employer insurance plans to cover mental health services at the same level as medical and surgical services if they offered them in order to make mental health service payments more equitable across illness categories; the effects of this on racial/ethnic minorities would thus only apply to those in the workforce and has not yet been studied.

BEYOND THE RHETORIC: DEFINING THE ACTUAL ACTIVITIES OF CC

On a clinical level, there is skepticism as to whether or not CC can be defined precisely enough to operationalize its aspects into clinical training and best practices. On an organizational level, many feel that CC is achieved once language accommodations are made, such as having interpreters available when needed and having key forms in translated versions. Hospital signs in multiple languages are now commonplace. While certainly necessary, these steps are not sufficient. But substantial progress has been made in isolating specific activities and defining and developing tools and products to promote activities of CC. We begin by making clear that CC activities need to occur on the multiple levels of a care organization in order to achieve quality outcomes.

Table 7.10–3.

National Standards for Culturally and Linguistically Appropriate Services in Health Care (HHS, Office of Minority Health, 2000)

Principal Standard:

1. Provide effective, equitable, understandable, and respectful quality care and services that are responsive to diverse cultural health beliefs and practices, preferred languages, health literacy, and other communication needs.

Governance, Leadership, and Workforce:

2. Advance and sustain organizational governance and leadership that promotes CLAS and health equity through policy, practices, and allocated resources.
3. Recruit, promote, and support culturally and linguistically diverse governance, leadership, and workforce that are responsive to the population in the service area.
4. Educate and train governance, leadership, and workforce in culturally and linguistically appropriate policies and practices on an ongoing basis.

Communication and Language Assistance:

5. Offer language assistance to individuals who have limited English proficiency and/or other communication needs, at no cost to them, to facilitate timely access to all health care and services.
6. Inform all individuals of the availability of language assistance services clearly and in their preferred language, verbally and in writing.
7. Ensure the competence of individuals providing language assistance, recognizing that the use of untrained individuals and/or minors as interpreters should be avoided.
8. Provide easy-to-understand print and multimedia materials and signage in the languages commonly used by the populations in the service area.

Engagement, Continuous Improvement, and Accountability:

9. Establish culturally and linguistically appropriate goals, policies, and management accountability, and infuse them throughout the organization’s planning and operations.
10. Conduct ongoing assessments of the organization’s CLAS-related activities and integrate CLAS-related measures into measurement

and continuous quality improvement activities.

11. Collect and maintain accurate and reliable demographic data to monitor and evaluate the impact of CLAS on health equity and outcomes and to inform service delivery.
12. Conduct regular assessments of community health assets and needs and use the results to plan and implement services that respond to the cultural and linguistic diversity of populations in the service area.
13. Partner with the community to design, implement, and evaluate policies, practices, and services to ensure cultural and linguistic appropriateness.
14. Create conflict and grievance resolution processes that are culturally and linguistically appropriate to identify, prevent, and resolve conflicts or complaints.
15. Communicate the organization's progress in implementing and sustaining CLAS to all stakeholders, constituents, and the general public.

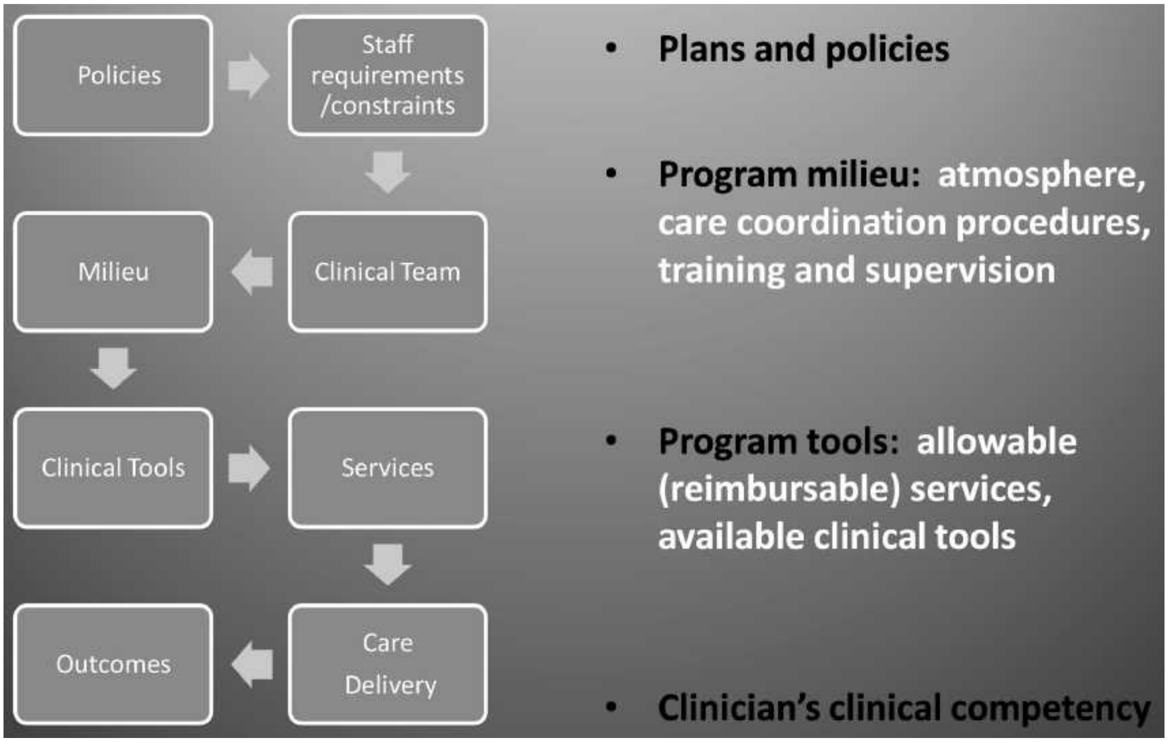
Figure 7.10–2 indicates that the policies and procedures of an organization impact the kind of staff employed and the limits placed on their therapeutic work. The composition of the clinical team, the kind of supervision that team members receive, and the approaches taken to coordinate care define the human resource boundaries of the program. The program's work is conducted within a palpable milieu that patients encounter and react to. Clinical work uses particular clinical tools and service delivery modalities that are constrained by reimbursement issues that impact service choices and the duration of delivery. The care that is ultimately delivered by clinicians is subject to their competencies.



- **Plans and policies**
- **Program milieu:** **atmosphere, care coordination procedures, training and supervision**
- **Program tools:** **allowable (reimbursable) services, available clinical tools**
- **Clinician's clinical competency**

FIGURE 7.10–2. Factors in a care organization impacting care outcomes.

Figure 7.10–3 illustrates how CC needs to guide these activities. The policies of an organization that works with multicultural populations need to address CC deliberately. The starting point is the incorporation of CC into a mission statement of the organization, allocation by the organization of a budget to enable a person/group to be assigned to spearhead CC, and the development of an organizational plan for CC. The plan requires community, provider, and client input. The desirability of staff diversity needs to be addressed in hiring policies, and training activities need to be organized for all levels of the organization. The clinical team needs to address cultural strengths and challenges when managing a client's care and coordinating services. The milieu of the program needs to be welcoming to cultural groups and accommodate their special needs, for example, by having convenient hours of operation, policies on privacy, and child-friendly areas. When delivering services, cultural assessments need to be made in order to appropriately diagnose the client and develop a service plan that will act to engage and retain the client in services. Services need to be chosen that are culturally acceptable to a client, and if sufficient numbers warrant it, services specifically chosen or adapted for cultural groups. In service delivery, clinical competency needs to be augmented with a requirement for CC as the behaviors of clinicians, based on their attitudes and skills, can impact outcomes.

Specific Clinical Activities

Psychiatrists play a key role in the engagement and retention of persons from cultural groups in care. They often are the gatekeepers for entry into specific types of services, determine specific treatments and serve as arbiters in treatment team meetings. In the clinical hierarchy, they have a distinct power role, thus impacting other clinicians as well as clients. CC is, however, not a concept discussed in most training programs and not yet a focus of clinical care, particularly in programs that strongly endorse medical models as explanatory of illness and symptoms and medications as the primary modalities of psychiatric care. Being clinically competent and practicing patient-centered care is endorsed and could include CC, but to date is only addressed in a hand full of training programs. But buy-in to CC by psychiatrists is critical to good care, as, in order to engage persons from cultural groups in care and to have them remain in care, they need to trust their psychiatrists. Lack of trust and feelings of stigma can impact engagement in services and adherence to treatment regimens. Trust can only be engendered if clinicians are cognizant of cultural views on mental illness that can impact treatment.

Cultural Competency Curricula for Clinicians

There are several curricula that address ways to enhance the CC of psychiatrists, counseling practitioners, psychologists, and social workers. A comprehensive review of such training guides has been conducted by researchers at the Canadian Centre for Addiction and Mental Health Centre de Toxicomanie et di Santé Mentale. They found consistency across guides in the use of the Sue and colleagues framework of CC encompassing personal level awareness, knowledge, and skills. Awareness modules address understanding and conciliating a client's and one's own biases, beliefs, attitudes, and world views. Antiracist and antioppression conceptual models may be invoked. Knowledge attainment addresses understanding both the generic cultural factors that can impact care, for example, social determinants of illness, level of acculturation, immigration status, as well as specific cultural factors such as a cultural view of illness causation and expectations for recovery. Skill component modules in the more practical guides suggest approaches for engagement and problem-solving based on cultural views of clients, as well as on the tangibles of working with interpreters and seeking consultation from clients' natural caregivers such as clergy and traditional healers. Case studies and scenarios are often introduced here. In addition, several guides also address clinician-client power relationships and even system–client interactions. In the former, sensitivity to issues of power differentials that can engender either trust or mistrust are addressed. In the latter, the curricula cover areas overlapping with recent ideas on structural factors impacting relationships.

We review in greater detail one curriculum developed by psychologists Deborah Altschul and Jeff Brooks-Harris for the broad swath of counseling practitioners. The multicultural skills training model (MST) is a practice-based method of CC that aims to enable providers to adapt their current practices to meet the needs of culturally diverse populations. It is applicable across a broad array of service modalities, including psychotherapy, psychoeducation, and skills training. It also draws upon the Sue and Sue tripartite seminal model of training offering practical approaches for understanding, in addition to the cultural views and biases of clients, one's own views and suggests ways to conciliate clinician-patient views. It addresses the need for practitioners to integrate into their therapeutic approach ways to empower clients to deal with the high likelihood of impacting social determinants of health such as housing needs.

MST is arranged as six clusters of culturally based activities to help better match the individuals' needs to therapeutic care. To illustrate, the module Becoming Aware of Your Own Multiple Worldviews, a prerequisite to working with multicultural clients, recommends confronting your own personal culture-based worldview as it influences views of mental health and the etiology of mental illness and appreciating your own multiple cultural identities and their impact on your thinking and treatment decisions. When working with clients, Creating a Culturally-Sensitive Working Relationship includes knowing the cultural norms and customs of a cultural group as they manifest in a particular individual and determining the style of collaboration that is most comfortable for the consumer. Understanding the Individual's Worldviews and Facilitating Cultural Identity Development parallels the work of the first caregiver module for the client and suggests exploring with clients the historical backgrounds of their cultures, as well as the current placement of the client in that culture. There is a focus on understanding cultural norms about help-seeking, problem attribution, and expected outcomes. On the client's part, it is helping the client to value their own cultural background but also to become open to other worldviews as well. Open discourse is suggested to help clients deal with experiences that they may have had that they perceived as racist or biased in social and work interchanges. In Responding to Societal Structures and Value, counselors are encouraged to work with consumers to confront their feelings of being undervalued because of cultural identity and social status. This could be based on having received slurs, felt racial discrimination, or having felt undervalued as transmitted to others in ambient societal messages. Empowering consumers through social activation and encouraging them to make greater use of cultural resources such as religious affiliations is recommended. A final cluster Utilizing Complementary Roles beyond Psychotherapy suggests ways to incorporate nontraditional healing methods of their cultures into the therapeutic work.

Clinician Self-Assessment of Cultural Competency

There are several practitioner-level CC self-assessment scales. While self-assessments can be pointless because of their subjective structure, if appropriately used, they can serve further as educational tools. One with established psychometrics that is widely used is the Multicultural Counseling Inventory. It addresses the three domains of awareness, knowledge, and skills. It is comprised of 40 items on which the provider rates his/her self-perceived cultural competence across the subscales Multicultural Counseling Skills (Sample Item: “When working with minority clients, I am able to quickly recognize and recover from cultural mistakes or misunderstandings”), Multicultural Awareness (Sample Item: “I am involved in advocacy efforts against institutional barriers in mental health services for minority clients”), Multicultural Counseling Relationship (Sample Item: “When working with minority clients, I find that differences between my worldviews and those of the clients impede the counseling process”), and Multicultural Counseling Knowledge (Sample Item: “When working with minority clients, I make referrals or seek consultations based on the client’s minority identity development).

Domains of Organizational and Program Activities

Except for that provided by psychiatrists or other professionals working entirely independently, most mental health care is organized as programs, bundles of available services, and treatment strategies geared toward ameliorating psychiatric distress. Programs, in turn, are components of mental health care agencies, centrally administered entities that provide policy and procedural guidelines for the programs under their purview and obtain and allocate resources. From an organizational or program perspective, CC activities should take place in the domains illustrated in Figure 7.10–4. Needs assessments refer to gaining an understanding of the diverse cultural groups using a care system, their possible service gaps, and specific service needs. Information exchange refers to mechanisms for receiving and transmitting information on community needs to persons responsible for planning and delivering services. Reflexively, deliberate efforts are required for communities to receive information on services available and ways to access these services. CC tools need to be disseminated to caregivers to improve their ability to provide CC services. Services that are offered need to be appropriate for community cultural groups and modifications to existing services made and/or new services introduced. Language accommodations may need to be made. Organizations need to promote and sustain recruitment, hiring, and retention procedures of culturally competent bilingual and bicultural staff, as well as to educate and train existing staff in CC. Linkages to other systems need to take into account the cultural needs of clients. Outcomes related to disparities in access and quality of care to cultural groups, desirable cultural group outcomes, and satisfaction with services need to be distinctly monitored. These activities are expected to improve outcomes and need to be monitored to see if they are taking place and the impact they may have. They need to be endorsed through the policies and procedures of the organization.

FIGURE 7.10–4. Cultural competency domains.

Both an organizational-level instrument and a program-level instrument to assess CC have been developed by the Nathan Kline Institute Center of Excellence in Culturally Competent Mental Health. The guiding principles were to have objective measures that demonstrated the importance of the concept of CC, for which it was feasible to collect appropriate data that were reliable and accurate. While clinicians can be assessed on their self-perceived attitudes and beliefs, organizational and program-level items were selected to be verifiable.

The organizational level scale items were selected based on a review of recommendations, standards, and guidelines. A 27-site study succeeded in establishing the predictive validity of the several language accessibility items of the scale, showing they correlated with better engagement and retention. The program level scale was based on an ethnographic study of three long-standing programs that defined cultural groups in which deliberate and culturally grounded steps had been taken to make them acceptable. Key and common elements were observed across these programs and used to define domains of CC. It is informative to review these instruments as they were designed in form not only for assessment purposes but intended to serve as roadmaps for introducing CC activities into organizations and programs. Each criterion is scored with an ordered scale of whether or not an activity is accomplished, reflecting an increasingly complex degree of activity related to CC. A score indicates that the listed activity and all those below it are carried out. We use the scale items to step through specific activities that should be undertaken to promote CC.

Organizational Activities

The first set of criteria is meant to ensure that a procedure for setting up a CC presence in an organization is established. Fundamental is that an organization has an articulated commitment to CC evident in its mission statement. By creating a position with an assigned budget and having this person/group part of the governance of the organization, there are tangible assurances that CC activities can take hold. Strategies for obtaining information about and working with members of diverse cultural groups include establishing a committee that includes members of the largest cultural groups in the community and empowering that group to review current CC work and communicate its concerns and ideas directly with management. The organization needs to identify which cultural groups are being served, what their language needs are, and which members of the community are not being seen in order to target its outreach efforts. Particular data items need to be collected for all clients in a consistent manner so that they can be aggregated to assess the cultures and language needs of the population being served by the agency. Information on the target community allows the agency to tailor its outreach and services to the needs of its cultural groups.

Several criteria relate to staff. Hiring, recruiting, and retaining staff that is from prevalent cultural groups or who have experience working with these groups is often noted as ideal. This diversity should extend beyond clinical staff to include administrative and supervisory staff as well. Organizations can have policies in place that seek culturally representative employees and strategies to identify suitable candidates. Staff training, if related to the work of staff, might be an effective way to enhance the CC of all, both members of cultural and mainstream groups.

Literacy level and English proficiency can be barriers to accessing services. Several criteria address language accommodation. This could be accomplished through hiring bilingual staff or, if not able to do so, having interpreter services available for all service users from the point of the first contact with the organization. Additionally, organizations need to recognize that key forms and documents need to be translated into commonly encountered languages in order to work effectively with persons having Limited English Proficiency. Furthermore, service descriptions and educational materials also need to be translated, and for persons with limited reading skills, alternate formats can be introduced (e.g., novellas, videos, and items in simplified English). Finally, services that do not appear to be effective for persons from certain cultural groups may need to be adapted for use with that cultural group, or new services introduced that have been developed specifically for prevalent cultural groups (Table 7.10–4).

Program Activities

The program-level CC assessment scale identifies activities that are more directly associated with delivering care than organizational activities. The criteria address strategies for engaging consumers from cultural groups into a program, measures program capacity for meeting the language needs of clients, including gaining an understanding of and working with communication styles of clients. The appropriateness of the services offered to the cultural groups served, the use of support groups including peers, family, and kin, and utilizing cultural community resources to sustain a consumer's recovery are also measured. The scale examines program outcome goals and prods a program to include in outcome measurement cultural groups' understanding of and desirability for different modes of recovery. Finally, keeping in mind the health care reform goal of population health, community outreach to cultural groups is assessed.

Engagement in a program means that the client will receive a sufficient dose of the program so that the maximum benefit of the services can be realized. If appropriately engaged, it is likely that participants will adhere to treatment regimens and complete the work of a program. Programs need to understand the cultural needs of their clients to engage them. A welcoming milieu in the program is essential as well. The scale measures whether assessments go beyond the collection of standard demographic information such as age, gender, race/ethnicity, and preferred language to include more detailed information on cultural group identity, level of acculturation, and religious/spiritual beliefs. Primary to engagement is addressing language needs and ensuring effective communication with clients through an understanding of and adjustment to their possibly different styles of communication. Examining ways to increase trust in the staff and addressing the experience of stigma from the perspectives of different cultures also increase engagement.

The scale examines whether services have been culturally modified or new culture-specific services have been offered. Certain service modalities may not be suitable for cultural groups. This is true even for some highly endorsed evidence-based practices. Exploring the possibility of making modifications to services to make them more culturally relevant can be accomplished with the input from members of the cultural groups and further ensures a connectedness of the program with the cultural groups it serves. For example, group therapy that requires sharing of personal information with strangers is not an acceptable mode of care for older adult Chinese populations. However, a mahjong group run by an experienced therapist can combine the positive aspects of both a culturally enjoyable experience and a profitable therapeutic encounter.

Utilizing various support groups available to the client can enhance the possibility of positive outcomes. The scale examines the extent to which the program includes peer staff from the cultural group. These are both paid employees and volunteers who have mental health experience. Staff from the same cultural groups of clients enrolled in the program who have mental health experience can facilitate engagement of cultural clients in the program by enhancing consumer trust in the program and providing role models of recovery. They can also provide other program staff with information on cultural views impacting mental health treatment and acceptable treatment strategies. Family and social networks–as identified by the consumer–can play a large role in the lives of members of cultural groups, particularly in immigrant groups. Some consumers may rely heavily on particular family members for their supports and for maintaining their ties to their communities, while others may rely more heavily on close friends and members of their social network. The extent to which these persons participate in assessment, care planning, and providing ongoing supports is assessed. The scale also measures the extent to which a program identifies community resources that are acceptable and responsive to cultural values and preferences of consumers as referrals to promote healthy community living.

The scale identifies three ways to measure outcomes, a critical aspect of any assessment of health care programs. Service delivery outcomes such as patterns of use and program completion rates, while not measuring the quality of care, should not differ among cultural groups and act as basic markers of disparities. Satisfaction surveys need to be formulated with members of cultural groups as their desirable recovery outcomes may differ from those of clinically comparable consumers from other groups because of different beliefs, relationships, and resources to achieve goals. Finally, a program’s outreach efforts are measured. In order to increase the enrollment of cultural groups into programs that might be of benefit to them, outreach efforts should be undertaken that include identifying these groups in the community and informing them about what the program offers to people from these cultures (Table 7.10–5).

Table 7.10–4.
Organizational CCAS Criteria and Their Rationale

Criterion	Description	Rationale
1. **Agency's Commitment to Cultural Competence**	The agency (or its parent organization [PO]) has a management-level person responsible for CC and a dedicated budget for CC activities, a CC plan, and procedures for updating the CC plan.	A management-level person who has primary responsibility for CC ensures that CC will be addressed. Without a dedicated budget, only limited activities can be conducted. A written plan concretizes the agency's commitment to CC. Review and updating ensure that there is a feedback loop and that corrective actions can be taken.
2. **Assessment of Service Needs**	The agency obtains current data on its service users and its target community that enable identification of their cultures and language needs	Particular data items need to be collected for all clients in a consistent manner so that they can be aggregated to assess the cultures and language needs of the population being served by the agency. Information on the target community allows the agency to tailor its outreach and services to the needs of its cultural groups.
3. **Cultural Input into Agency Activities**	The agency (or its PO) has a CC Committee or other group that addresses cultural issues and has participation from cultural groups of the target community	A committee dedicated to CC will enhance the likelihood that activities appropriate to the cultures served are introduced and carried out. The committee can go under many names or be part of the functions of existing boards, advisory groups, and committees.

		Input is sought from representatives of the most prevalent cultural group of the target community. Having more than one representative from a cultural group makes active participation more likely.
4. Integration of CC Committee or Other Group with Responsibility for CC Within Agency	The CC Committee or other group with responsibility for CC is integrated within the agency evidenced by the following activities: ▶ Reviews services/programs with respect to CC issues at the agency ▶ Reports to Quality Assurance/Quality Improvement program of the agency/PO ▶ Participates in planning and implementation of services at the agency ▶ Directly transmits recommendations to the executive level of agency/PO	The extent to which the functions of the CC Committee are reported and used in the agency provides a measure of the likelihood of change with respect to CC. Four key committee functions are expected to take place, but they may be introduced at different stages.
5. CC Staff: Training Activities	The agency (or PO) offers to staff educational	Training and educating staff in CC enhances the likelihood of the delivery appropriate

	activities in which cultural issues are addressed and requires staff to have an adequate amount of specific training on CC	services to cultural groups. Ideally, educational activities should take place every year, and all staff members who have face-to-face contact with and provide direct clinical care to agency clients receive CC training. Administrative staff should also be knowledgeable about CC.
6. **CC Staff: Recruitment, Hiring, and Retention of Staff from/or Experienced with the Most Prevalent Cultural Groups of Service Users**	The agency is committed to hiring and retaining CC staff who are from or who have had experience working with the most prevalent cultural groups of its service users	Having direct service, supervisory and administrative staff with relevant experience with the most prevalent cultural groups enhances the likelihood of the acceptability and use of CC practices. Hiring and retaining professional staff members who are from the cultures of service users provides positive role models for clients of the agency and affords additional opportunities to increase knowledge about the cultures.
7. **Language Capacity: Interpreters**	The agency (or PO) accommodates persons who have limited English proficiency (LEP) by using interpreter services or bilingual staff	Language needs of persons with limited English proficiency must come to the attention of the agency at the point of first contact in order to identify their needs and link them to the appropriate services. Once a person has agreed to

		receive the services offered by the agency, language needs must continue to be addressed. Ideally, interpreters are formally trained and certified or are bilingual staff members who have received CC training.
8. Language Capacity: Bilingual Staff	The agency has staff who speak the language of the most prevalent cultural group of service users with members who have LEP	Having bilingual staff members who can work directly with persons with language needs is ideal–and likely to be cost-effective as well.
9. Language Capacity: Key Forms	The agency has translated versions of key documents and forms in the language of the most prevalent cultural groups of its service users	Legal documents and critical care information must be understandable to persons with limited English proficiency to ensure that such information is provided equally to all service users.
10. Language Capacity: Service Descriptions and Educational Materials	The agency accommodates persons with LEP by translating service descriptions and accommodates persons with limited reading skills (LRS) by providing service descriptions or educational materials in formats	Using different formats and media for descriptions of available services and for educational materials ensures that literacy level is not a barrier to accessing services. Service-related materials translated into the most prevalent non-English language will be especially helpful to overcome treatment barriers for

	they can understand.	service users and family members.
11. Assessment and Adaptation of Services	The agency (or PO) reviews and adapts or introduces services suitable to the most prevalent cultural groups of service users	A comprehensive CC-based assessment of services may result in the adaptation of existing services and the introduction of new services to better serve members of the most prevalent cultural groups.

Table 7.10–5.
Program Level CCAS

Criterion	Description	Rationale
1. Cultural Assessment of Consumer	Program obtains a detailed cultural assessment of each consumer that is additional to collecting standard (age, gender, race/ethnicity; preferred language) demographic information	Information that provides a view of beliefs, values, and world views of the consumer that can be used to improve diagnosing and the therapeutic alliance of staff with cultural groups. Information is recommended to be collected at the initial clinical assessment but can be updated throughout the course of the program. Cultural information should be made available to all clinical staff and care workers.
2. Engagement: Spoken language capacity	Program has procedures and staff to facilitate working with consumers/families with limited English proficiency or with consumers who are Deaf	If staff can communicate with consumers/families in their preferred language, the therapeutic encounter will be enhanced.
3. Engagement: Communication styles	All levels of program staff communicate with persons from cultural groups in ways that are respectful to them	Barriers between staff and consumers are reduced when modes of communication are respectful, acceptable, and familiar to the consumer.
4. Engagement: Trust building	Program intentionally and actively works to build and maintain the trust	Retention and engagement in the program are likely to increase if consumers feel their personal information

	of consumers and family members from cultural groups	is held confidential and that staff care about them by being responsive to their values and preferences as they relate to the program.
5. Engagement: Culturally framed stigma reduction	Program intentionally conducts activities to reduce stigma of mental illness as experienced by a cultural group	Stigma can impede engagement in services. Persons from cultural groups who might benefit from mental health services often delay seeking treatment or drop out of services because of the cultural group’s views of mental illness, including their attribution of its causes, its impact on other family members, and their social standing in their communities.
6. Culturally friendly service delivery environment	Program is conducted in physical spaces that are made appealing and familiar to the cultural groups served	Features of surroundings that are familiar, welcoming to families, and celebratory of a cultural group enhance consumer and family feelings of comfort and a sense of connectedness while participating in the program.
7. Culturally modified or new services	Program has strategies for making their services responsive to values and preferences of persons from	Services need to be reviewed and modified for applicability and their responsiveness to the values and preferences of the cultural group. New services may need to be developed.

	cultural groups with the aim of improving their effectiveness	
8. Inclusion in program of staff from cultural groups who have mental health experiences (consumer peers)	Program includes staff, both paid and volunteers, who have mental health experience and are from the cultural groups served by the program	Staff from the same cultural groups of clients enrolled in the program who have mental health experience can facilitate engagement of cultural clients in the program by enhancing consumer trust in the program and providing role models of recovery. They can also provide other program staff with information on cultural views impacting mental health treatment and acceptable treatment strategies.
9. Family member involvement	Program engages persons that are identified by the consumer from their family, including from social networks, to take part in care planning and providing ongoing support	Family and social networks can play a large role in the lives of members of cultural groups, particularly immigrant groups. Some consumers may rely heavily on particular family members for their support and for maintaining their ties to their communities, while others may rely more heavily on close friends and members of their social network.
10. Community resources	Program utilizes community	Consumers from cultural groups benefit from

	resources acceptable and responsive to cultural values and preferences of consumers to promote health outcomes	interventions that involve the use of community resources.
11. Satisfaction with Program	Program conducts activities to measure consumer and family member satisfaction with the services provided	Program improvement for cultural groups needs to be based on consumer and family member appraisals of the program.
12. Service Delivery Outcomes	The program examines disparities in service delivery outcomes related to engagement and retention in the program	Service delivery outcomes for cultural groups should not differ from those of clinically comparable consumers from other groups. Consumers from cultural groups may have particular difficulties in engagement in and retention of services. Differences in service delivery measures on engagement and retention could reflect these difficulties. These need to be identified and monitored by the program.
13. Recovery Outcomes	The program examines disparities in service process outcomes and	Recovery outcomes for cultural groups may differ from those of clinically comparable consumers from other groups because

	identifies and monitors recovery outcomes that are desired by consumers from cultural groups	of different beliefs, relationships, tools, and resources to achieve goals. These need to be identified and monitored by the program.
14. Program Outreach	Program identifies cultural groups in the community/service area who underutilize services and might benefit from the program and conducts outreach to increase their access	To increase the enrollment of cultural groups into programs that might be of benefit to them, outreach efforts should be undertaken that include identifying these groups and informing them about what the program can offer.

IN CONCLUSION

The mental health field has grappled with the complexities of psychiatric disabilities in an increasingly multicultural population. Clinicians need to be aware of and respond to more and more inclusive federal legislation focusing on nondiscrimination and the national standards for the promotion of CC in hiring practices and health care delivery. Current health care reform efforts are resulting in new models of integrative care that address Donald Berwick’s triple aims for the improvement of population health, higher quality care, and cost reduction. Clinicians can work from the ground up to incorporate CC into the new models providing an opportunity to better fulfill the triple aims. Population health requires knowing and understanding the needs of diverse cultural groups; higher quality care requires CC of organizations, programs, and clinicians. Cost reductions will follow if care is more appropriately targeted to cultural groups resulting in reduced use of expensive and inappropriate services. Systemic changes, as alluded to in organizational CC and structural competency, provide an outline for the necessary systemic changes. Clinicians, including psychiatrists and other mental health professionals, are the critical lynchpin in successful treatment encounters, so along with systemic change, clinician changes in attitudes and behaviors may act to shift the entire system toward the goals of CC.

7.11 Medical Error

NORA C. OBERFIELD, M.D.

Doctors and the medical systems within which they practice strive for perfection in patient care. Nevertheless, as humans and technology are imperfect, medical errors occur in spite of this dedication to excellence. A landmark 1991 Harvard Medical Practice Study estimated that as many as 1.3 million injuries occurred nationwide to patients receiving hospital care. In 1999, the IOM warned the public that between 44,000 and 98,000 Americans may die each year as a result of medical errors. In 2013, in the *Journal of Patient Safety*, John T. James gave updated estimates of deaths associated with medical error during hospitalization based on studies published between 2008 and 2011. He estimated that more than 400,000 premature deaths occurred in hospitals per year related to preventable patient harm. That number is far greater than the estimate previously reported by the IOM, suggesting that there continues to be much room for improvement in this area. In 2016, the *British Medical Journal* noted medical error as the third leading cause of death in the United States. In 2019, the World Health Organization (WHO) reported that there is a 1 in 300 chance of a patient being harmed while receiving medical care. Too often, inherent bias related to race, ethnicity, gender, sexuality, and socioeconomic status also impacts who is more likely to experience a medical error. In 2018, in the *International Journal for Equity in Health*, researchers concluded that women and African-Americans were affected more than other groups.

Although a number of congressional actions have led to legislation requiring mandatory national or state reporting by hospitals of medical errors, reports of such documentation have been scarce. Issues to contend with are the need to protect doctors and hospitals from frivolous lawsuits resulting from public disclosure and failure to maintain confidential information about patients. While more hospitals are engaging in patient safety initiatives, a 2021 *Journal of Patient Safety* study found that these interventions have only been minimally effective in medical error risk reduction.

The topic of medical error has been complicated by the use of confusing and often conflicting terminology. The IOM separates medical errors into two main categories: errors of execution and errors of planning. An error of execution occurs when there has been a “failure to complete a planned action as intended,” and an error of planning occurs when there has been “the use of a wrong plan to achieve an aim.” Thus, by definition, medical errors require that there be a component of negligence. When they do occur, there is a desire for attribution to try to understand why the errors have happened. Did the error occur because the physician departed from an accepted standard of treatment? Was the error avoidable, or the result of poor training? Or was it unintentional—an accident—and better considered a close call or a borderline case?

It is important to distinguish medical errors from adverse events. The latter are related to a particular disease process and are most often predictable or, if not predictable, are known risks. Medical errors usually lead to adverse events and may harm the patient temporarily or permanently, may increase the time for recovery from disease, or may result in patient death. Adverse events may occur in the absence of medical errors, and medical errors may not be associated with an adverse event.

At Johns Hopkins University, the term medical mistake is used instead of medical error and is defined as follows:

> A medical mistake is a commission or an omission with potentially negative consequences for the patient that would have been judged wrong by skilled and knowledgeable peers at the time it occurred, independent of whether there were any negative consequences. This definition excludes the natural history of disease that does not respond to treatment and the foreseeable complications of a correctly performed procedure, as well as cases in which there is reasonable disagreement over whether a mistake occurred.

Types of Error in General Medicine

The current literature highlights five main types of medical errors: errors of commission, errors of omission, errors of communication, errors of context, and diagnostic errors.

1. An error of commission occurs when something done by a member of the medical team leads to patient harm either because it was the wrong thing to do or because it was the correct thing to do, but it was not performed correctly.
2. An error of omission occurs when something that was clearly needed for the patient’s healing process was not done.
3. An error of communication occurs when information is not conveyed effectively, either between at least two providers of care or between a provider of care and the patient.
4. A contextual error occurs when a member of the health care team does not recognize social factors in the patient’s life, which could

create barriers to the implementation of effective postdischarge treatment.
5. Diagnostic errors occur when a wrong diagnosis is made, which could have sequelae such as inappropriate or delayed treatment.

Errors may also be categorized as systematic or individual. Systematic errors are caused by flaws in the hospital system or in the transfer of information from one unit of the hospital or from one group of doctors to another. In general, no one person is to blame. An example would be the unavailability or inability to retrieve a patient's medical records or a mismatched blood transfusion. The failure is in the health care delivery system as a whole rather than in the individual.

Individual errors are attributed to a particular physician or to a specific member of the treatment team. Examples include prescribing the wrong medicine or operating on the wrong leg. The physician bears the responsibility, even if the error is made by a person under his or her supervision. Research at John Hopkins Medical Center involving an examination of 25 years of U.S. malpractice claim payouts from 1986 to 2010 indicated that diagnostic errors were the most common type of medical error. A 2020 report from AHRQ suggests that diagnostic errors remain prominent at this time. While the predominant focus in recent years has been on reducing medication and surgical errors, the importance of improving the error rate in the diagnostic area is equally important.

Types of Error Specific to Psychiatry

While there is increased discussion of medical error generally, errors occurring in patients with primary psychiatric diagnoses are an area often excluded from the literature. S.W. Cullen and colleagues separated errors in inpatient psychiatry units into four categories: treatment errors, diagnostic errors, preventive errors, and other errors.

1. Treatment errors are defined as "…failures in the formulation or delivery of an appropriate intervention, therapy, or procedure."
2. Diagnostic errors are not only inappropriate psychiatric diagnoses but also mistaking a physical illness for a psychiatric condition or vice versa.
3. Preventive errors were the most common and have been defined as "any failure to offer indicated prophylactic treatment, as well as

inadequate or inappropriate monitoring of an initiated treatment plan." Preventive errors include inadequate or disruption of safety protocols "…such as fall precautions, locked unit doors, break-away bars in closets, or 15-minute checks for patients with suicidal ideations."

4. The "other errors" category included problematic transfers and discharges.

In the Cullen study mentioned above, it was found that nonpsychiatric staff members felt ill-prepared to deal with referrals of patients with a history of psychiatric treatment or hospitalization or of patients who were in a state of emotional distress. There was often an inadequate or cursory medical examination in patients who were disruptive or otherwise uncooperative. In order to reduce the error rate among such patients, it will be necessary to decrease stigma about mental illness and educate all health care providers about the complicated presentation of some psychiatric patients with active symptoms such as psychosis. In addition, compliance issues may be a factor in the management of psychiatric patients with a medical illness which may cause difficulties implementing safe and appropriate discharge plans.

Causes of Error in General Medicine

As mentioned above, the causes of medical errors are multifactorial. In general medicine, they include medication errors, transitions of care errors, errors stemming from the use of EMRs, errors related to the challenges of treating a growing geriatric population, and errors related to job overload, fatigue, and physician burnout, among others discussed below. In most instances, medical errors correlate with inexperience. For example, first-year house officers make more errors than second- and third-year residents. Junior attending physicians make more errors than senior attending physicians. Clearly, the aphorism of experience being the best teacher seems to apply in these instances, but experience or the lack thereof is not the only factor.
